ACKNOWLEDGEMENTS

As I look back over the last 23 years of my life, I realize that I have met a handful of key individuals to whom I owe a great deal, as I truly believe that I wouldn't have ended up here without their input in one form or another.

I would like to express my gratitude to my supervisor, Prof. Dr. Miguel Mira da Silva, whose expertise, motivation, encouragement, understanding and patience, added considerably to my graduate experience. I appreciate his vision, aging, ethics, interaction with participants and his assistance in writing reports. I would like to thank the other members of my advisory team, Dr. José João Costa and Eng. Gonçalo Carvalho for the assistance they provided at all levels of the research project and for taking time out from their busy schedule to serve as my external reader.

I would also like to thank my family for the support they provided me through my entire life and in particular, I must acknowledge my best friend, Juliana, without whose love, encouragement and editing assistance, I would not have finished this thesis.

ABSTRACT

The importance of network topology discovery cannot be denied, especially for tasks like network management and network auditing. Given the dynamic nature and the rising complexity of today's IP networks, manually keeping track of topology information is an overwhelming task.

For an accurate network discovery, almost all evaluated solutions require the configuration of SNMP agents on nearly all network devices, a requirement only feasible within a network management approach. In practice, several algorithms have been designed to either perform in a predefined or predicted manner, otherwise providing evidence to be ineffective at all. This situation clearly persuades the development of effective, intelligent and general-purpose algorithmic solutions for automatically discovering the latest physical topology of an IP network. We describe a novel approach of a network discovery technique as a result of combining several scanning methods and an intelligent algorithm, and propose a customized vulnerability scan engine.

As a result, we implemented and evaluated this extremely efficient “all-in-one” vulnerability assessment framework on three different network case studies, demonstrating its effectiveness.

RESUMO

A importância da descoberta da topologia de rede não pode ser negada, sobretudo para tarefas como gestão de rede ou auditoria de rede. Dada a natureza dinâmica e a crescente complexidade das redes actuais, manualmente manter a informação de mapeamento de rede é uma tarefa imensa e desnecessária.

Para uma rigorosa descoberta de rede, sensivelmente todas as soluções avaliadas exigem a configuração de agentes SNMP em quase todos os dispositivos de rede, um requisito que só pode ser garantido numa abordagem de gestão de rede. Os algoritmos existentes funcionam de um modo predefinido ou previsto, que na realidade não se revelam eficazes. Esta situação persuade claramente o desenvolvimento de soluções algorítmicas eficazes, inteligentes e de aplicação geral, para descobrir automaticamente a actual topologia física de uma rede IP. Esta nova abordagem ocorre como resultado de combinação de vários métodos de descoberta de rede em conjunto com um algoritmo inteligente e um mecanismo de identificação de vulnerabilidades perspicaz.

Como resultado, implementámos e avaliámos, em três diferentes casos de estudo, esta framework “tudo-em-um” de reconhecimento de vulnerabilidades numa rede, revelando-se extremamente eficiente.

1. INTRODUCTION

1.1. THE EVIL INTERNET

Lately, the Internet has experienced a phenomenal growth. Several connections have spread and continue propagating at a speed never seen before in any other type of network. Today, the Internet is a vital resource that is changing the way many organizations communicate, interact, and do business [1].

With the arrival and expansion of the Internet and because it was not anticipated to be safe, the number of external people who can potentially make their way “inside the company’s walls” has multiplied exponentially. An odd criminal category has emerged: commonly known as hackers, serious computer enthusiasts focusing on host vulnerability information are responsible for virtually assaulting educational institution systems, government agencies, international and profitable enterprises, often causing damage and disorder to these organizations. Hackers are well-paid to extract information such as social security, credit card or bank account numbers, as well as usernames and passwords from company files.

These economically motivated efforts to infiltrate a company’s network present significant costs and liabilities. In addition to the risk of direct losses, there are also significant impacts to staff productivity.

As it is never impossible for a hacker to break into a computer system, only improbable [2], companies are increasingly held accountable by government agencies and shareholders for properly securing the consumer data they retain. Failure to do so can result in legal charges, fines and a damaged reputation [3].

1.2. ESSENTIAL TERMINOLOGY

Before we can move on to the tools and techniques, we shall look at some of the key definitions. The essence of this section is to adopt a standard terminology through the manuscript.

- Threat – An action or event that might prejudice security. A threat is a potential violation of security;
- Vulnerability – Existence of a weakness, design, or implementation error that can lead to an unexpected, undesirable event compromising the security of the system;
- Attack – An assault on system security that derives from an intelligent threat. An attack is any action that attempts to or violates security.
- Exploit – A defined way to breach the security system through vulnerability.

1.3. SECURITY THREATS

Today, since the vast majority of intellectual property, customer information and trade secrets, are created and stored in digital format, data security is a top priority for every company. Loss of physical assets such as laptops and storage media that contain highly sensitive and valuable data, as well as intentional criminal or malicious activities from within the organization caused by a displeased employee, remain significant risks to data security that need to be addressed in a company's approach to protecting information assets.

Every day, the news media give more and more visibility to the effects of computer security on our daily lives. For example, on a single day in June 2006, the Washington Post included three important articles about security. The fact is that news like this appears almost every day, and has done so for a number of years. There is no end in sight [4].

The United Kingdom's Department of Trade and Industry (DTI) commissioned PricewaterhouseCoopers LLP to conduct an Information Security Breaches survey in 2006 that found that 99% of companies were connected to the Internet, and over 80% of the large companies surveyed suffered a security incident within the preceding year. Websites continue to be a leading source for malware infections: the Threat Research Team at Webroot Software identified exploits on over 3 million web sites in 2006. According to a market research study conducted in January of 2007 (check Figure 1), over one-third of enterprises surveyed dealt with Trojan horse attacks (39%) and almost one-fourth dealt with system monitor attacks (24%) [3].

Figure 1: Market Research Study – Malware Infections [3]

As systems generally become more secure, methods used by hackers are becoming more advanced, involving intricate repositioning, social engineering, physical compromise, and use of specific exploits to bypass traditional security defenses like firewalls or other perimeter solutions to attack peripheral software components such as antivirus or backup solutions widely deployed within corporate networks.

Table 1 summarizes how the distribution and infection methods as well as the required removal techniques have evolved since 2004 [3].

Table 1: Threat Evolution [3]

	2004	2005	2006
Type	<ul style="list-style-type: none"> • Benign Adware • Randomized Hijacks 	<ul style="list-style-type: none"> • Malicious Adware • Trojans 	<ul style="list-style-type: none"> • Targeted/Custom Trojans • Phishing Trojans
Distribution	<ul style="list-style-type: none"> • Web sites 	<ul style="list-style-type: none"> • Bit Torrent • Peer-to-Peer (P2P) • Piggybacking 	<ul style="list-style-type: none"> • Email • Internal Hacking
Infection	<ul style="list-style-type: none"> • File Placement / Naming 	<ul style="list-style-type: none"> • DLL Injection • Browser Helper Object (BHO) 	<ul style="list-style-type: none"> • Modifying Executables
Removal	<ul style="list-style-type: none"> • Deleting on Disk • Deleting Registry Keys 	<ul style="list-style-type: none"> • File Neutering • Correlation Removal 	<ul style="list-style-type: none"> • Driver-based Removal • Dynamic Conditional Removal

Security breaches reflect not only on the information assets compromised but also on the image of the corporation, which can have an adverse effect on partnerships and also customer base.

A 2002 CSI/FBI computer crime and security survey, noted that 90% of the respondents had detected security breaches and only 44% were able to quantify the losses occurred; this alone amounted to an amazing \$455,848,000. This is a sharp increase from previous year's figures of \$170,827,000 (theft of proprietary information) and \$115,753,000 (financial fraud) [5].

It is evident therefore, that the current e-business scenario warrants extreme caution while administering security configurations to the computing infrastructure. While the above-mentioned aspects are not exhaustive, they can be cited as the predominant reasons why organizations and system administrators have to equip themselves with tools and methods to circumvent vulnerable scenarios towards achieving organizational objectives.

1.4. DE-PERIMETERIZATION

The hardened perimeter walls that are essential for network security are becoming more and more porous and will continue to do so over time. Moreover, this is happening at the worst possible time: when the value of the data being protected is greater than ever. The perimeter is still a strong defense, but it is losing its effectiveness. Security is all about being proactive, identifying threats and dealing with them before they cause harm [6].

Until now, the basic architecture for network security has always been a given; a hardened perimeter to separate the trusted “insiders” from the un-trusted “outsiders.” This is an electronic version of a physical defense model. It’s how we have protected our people and assets since mankind first established villages. Looking back in history, villages, towns and entire cities once were once protected by enormous perimeter walls. The walls were seen throughout Europe, the Middle East, and even China. They were effective for a time, but intruders soon discovered ways around, over or under them, and eventually became so ineffective that they were no longer built. Communities eventually transitioned to new ways of providing a secure environment for their residents.

One development was the evolution of natural neighborhood “zones” where outsiders became immediately evident, and were watched. For years these “neighborhood watches” worked, but as more people became more mobile, and the world became “smaller”, it became further difficult to discern the insiders from outsiders. Consequently, the base security model moved to “coordinated end point” security, where each house is locked with its own deadbolts and secured with its own alarm system, feeding through direct connection or via “911” into centralized response and control systems. This evolution in the physical world from city wall, to trusted neighborhood community, to point based security may help point the way to where the basic network security model needs to go.

Since the environments are completely different, securing inside the perimeter is radically different than securing the perimeter and beyond. Securing from the outside, in terms of authentication, authorization, access control, and encryption, is relatively easy as all connections flow through a small number of access points, considering that security is managed at these gateways.

In a fully de-perimeterized network, every component must be independently secure, requiring systems and data protection on multiple levels, to disclose vulnerabilities from inside the perimeter.

1.5. MITIGATING VULNERABILITIES

Various network-centric mechanisms are being developed to diminish vulnerabilities. Firewalls, IDS and IPS, as well as antivirus software are just a few. Firewalls are used to prevent and allow traffic flow based on a predetermined policy. They need to work in conjunction with IDS/IPS systems to modify its rule set based on perceived intrusions. Much research and development has made this approach realizable. Still, because the network changes with the addition of new links and new components, a firewall solution may not be implemented at the newly or modified network area.

Additionally, as the process of notifying the security team of the modified network structure is usually lacking or deficient, a solution is needed to remove the human responsibility component from this security infrastructure, automatically producing a change notification when network devices or protective measures are deployed. It's clear that human interaction will always be needed for various security related issues, but not at the expense of a change notification process.

1.6. NETWORK SECURITY ASSESSMENT

As it will be shown later, there are several methodologies to evaluate the security state of a specified network. In theory, the purpose for conducting penetration tests would be to identify technical vulnerabilities in the tested systems in order to correct its vulnerabilities and mitigate any risk. In most environments, vulnerabilities and exposures are due to poor system management, uninstalled patches, weak password policies, or poor access control. As a result, the principal reason and objective behind penetration testing should be to identify and correct the underlying systems management process failures that produced the vulnerability detected by the test.

Additionally, even as a pure technical security evaluation methodology such as a security assessment presents the ability to gain a much deeper understanding of the threats, vulnerabilities and exposures a modern network faces, contrary to what may seem intuitive, a security assessment is not simply a technology solution. It involves the efforts of every level of an organization, technologies and processes, used to design, build, administer, and operate a secure network.

Evaluating the security state is the first step any organization should take to start managing information risks correctly. In fact, a more proactive approach to risk management is taken when reviewing a network in the same way a determined attacker would do. The best practice methodology used by attackers and network security consultants involves three distinct high-level components [2]:

- Bulk network scanning and probing to identify potentially vulnerable networks and hosts;
- Investigation of vulnerabilities and further network probing by hand;
- Exploitation of vulnerabilities and circumvention of security mechanisms.

1.7. PROBLEM & REQUIREMENTS

We have all heard the phrase, “There is more than one way to skin a cat.” When it comes to technology in the information security profession, there are plenty of choices. There are different tools available for a given task. Currently, as choosing the correct tool depends on several factors and no single tool can do it all, relying on only one tool is unwise for most tasks [7].

The consulting firm that is collaborating with my study clearly persuades the development of an “all-in-one” vulnerability assessment framework in order to:

- Accurately determine all active network assets, without concern to the network environment;
- Produce the lowest disturbance on the network;
- Require no input information at all;
- Efficiently produce a quick initial response to the process;
- Wisely generate the network topology;
- Intelligently assure a vulnerability scan practice.

1.8. SUMMARY

From the abovementioned components and requirements, this document covers a personalized framework to determine the security state of a given network, by providing a newly intelligent and pioneer approach to network scanning and probing, along with vulnerability identification.

The framework identifies accessible hosts and network services that can be harmed in order to gain access to trusted network divisions and begins a comprehensive analysis to investigate the latest vulnerabilities in accessible network services, including technical details of potential vulnerabilities along with tools and scripts to qualify and exploit the present vulnerabilities.

2. RESEARCH AREA

As stated before, the primary reason and objective behind the methodologies in charge of evaluating the security state of a specified network is to identify and correct the underlying system management process failures that produced the identified vulnerabilities. Adding to the fact that the maintenance of security in IT organizations requires lots of work and concentration from network administrators, it's crucial to describe three related and yet distinct principles that help IT departments manage their software and equipment:

- Auditing
 - Established compliance procedure used to satisfy legal or regulatory obligations;
 - Reveals the conformity level and risk of the achieved security rank, based on the industry, regulatory, or legal requirements.
- Assessment
 - Internal initiative used to create a baseline picture of a network's security;
 - Usually for the purpose of making improvements.
- Management
 - Helps to detect and track faults and changes related to all active IT assets;
 - Monitors and implements the required procedures to prevent eventual exposures.

The following chapters describe the network security auditing, network security assessment, and network management principles in such way that, if combined and used effectively, contribute to assure higher levels of security on enterprise network systems. Assembling these clarified principles with an assortment of network scanning methods and algorithms, it's possible to achieve a comprehensive network description, through efficient and accurate techniques, and automatically produce a change notification when network devices or protective measures are deployed.

2.1. AUDITING

In order to be able to obtain information about IT assets during a network audit, there are a couple of basic requirements that must be met regardless of which particular audit system is used.

Firstly, and most obviously, no one can audit something if unaware about its presence. The auditor must be able to detect the existence of the IT asset that he wants to interrogate (asset detection). Secondly, once he knows the asset truly exists, the auditor has to be able to interrogate it for further information (asset auditing).

2.1.1. BASIC CONCEPTS

Auditing agents are applications or utilities that collect information about the devices in the organization. Once that information has been collected it can be posted directly to a repository to be handled at a later date.

The auditing agent tools can be divided into two main categories [8]:

- Network Auditing Agents – used to find and audit machines for the entire network;
- Machine Auditing Agents – used to audit and collect information about an individual machine.

Consecutively, there are three different ways to accomplish the asset auditing task:

- Audit IT assets remotely, over the network, using a single network auditing agent;
- Install an auditing agent on every machine, collecting the information about the asset;
- Manually collect information about each IT asset.

The following sections discuss each of these three methods.

Network Auditing Agents

The benefit of remote audits is that the auditing agent only needs to be installed on a single machine rather than on every machine to be audited. However, the desired information may not be accessible due to some serious attention to network security. Additionally, it involves the transfer of a certain amount of data between the auditing agent and every active machine, which may cause some performance implications.

The basic requirements that the auditing agent must meet in order to be able to audit machines remotely are:

- Either be aware of or be able to discover the network resources;
- Successfully connect to each of the machines to be audited;
- Interrogate (audit) each machine in order to obtain the required information;
- Store the collected information in a specified repository.

Machine Auditing Agents

This approach is simpler than the network auditing agents, since it does not have to establish any network connection to the machine that it will be auditing (which simplifies security and communication problems), even allowing the audit of non-detectable machines. In addition, unlike the network auditing agents' technique, after each audit, the tool does not post the information that it collects back to the repository, so no network connection is required at all.

However, this also presents some technical challenges:

- The auditing agent must be deployed / run on each of the machines to be audited;
- Once the agent audits a machine, one has to work out a way of getting the information that it collects back to the central repository, so that it is available to technicians and administrators on the IT department.

Manual Auditing

There are no complex protocols to be understood or basic technical requirements that must be met in order to manually record the existence of a particular device. Anyway, it should be possible to manually record managed equipment and software on the storage area, accumulating different kinds of information – for example recording a particular piece of equipment as a spare part of a machine.

2.1.2. SECURITY AUDIT

As declared before, information security encompasses more than just IT systems – people who use the systems can also inadvertently open security breaches. A security audit aims to detect and highlight any problem areas within the IT infrastructure and staff behaviors.

Information security is characterized as the preservation of confidentiality, integrity and availability of the information under control, and is achieved by implementing a suitable set of controls – policies, practices, procedures, organizational structures and software functions.

Concept

In essence, a security audit is a policy-based assessment of the procedures, practices, and systems of an organization, and involves assessing the risk level produced by its normal operational actions.

Even though it is possible to choose to center the audit on different areas, such as firewalls, hosts or even whole networks, more focus should be placed on regular internal security audits and more frequent vulnerability tests. However, a security audit may also address issues with the organization's IT systems, including software and hardware, its infrastructure, procedures, business processes and people.

In any case, when performing a security audit, it is important to look beyond the IT systems and consider also the human interface to the IT system. The system may be technologically perfectly secure, but some users may be involved in practices that compromise the security of the IT systems in place. As a result, any audit must attempt to identify all the possible risks. IT systems are at risk from compromise from a number of sources, including poorly-managed or badly-configured systems, internal users, external users and external attackers. Even authorized system users can be the source of a security breach, so identifying possible lapses that could allow this is just as important as preventing external attack.

Once the audit has been completed, the result includes the compliance level information of the users and systems under control with a risk exposure and security level idea of these systems, as well as the potential damage that could occur if the worst came to the worst – enabling the opportunity to plan and develop a strategy to ensure minimal damage.

2.1.3. AUDITING TOOLS

Over the last few years a number of tools have been developed to aid the system administrator. These tools run on a number of platforms including Microsoft Windows, Linux, Solaris and FreeBSD. There are numerous types of tools: those that detect changes in system configuration; tools that test for known security issues; and a class of tools that are used to monitor systems in real time, such as network sniffers. Table 2 shows a small selection of the audit tools that are available in the market today.

Table 2: Examples of Auditing Tools

Tool	Platforms	Description
COPS / Tiger	Linux, Solaris	Change / Intrusion Detection
Xprobe 2	Linux, Solaris	Active OS Fingerprinting tool
L0phtCrack (LC5)	Windows	Password Cracking
ISS / IBM Internet Scanner	Windows, Linux, Solaris, HP-UX	Vulnerability Scanner, Network Information
Nmap	Windows, Linux, Solaris	Port Scanner, Network Information, OS Fingerprinting
TCPdump	Linux, Solaris	Network Monitoring
SniffIt	Linux, Solaris	Network Monitoring
CyberCop Security Scanner	Windows, Linux	Port Scanner, Password Cracking, Network Information
TripWire	Linux	Change / Intrusion Detection

These gather a vast amount of information based on what the tools have pre-programmed into them. They automate the processes of gathering information and are extremely useful, as they can be set off running and usually require little user intervention, thus saving a large amount of time in the process [9].

2.2. ASSESSMENT

Recent historical events such as September 11, 2001 have raised the bar significantly in terms of security requirements. Security assessments are something that every organization should periodically perform.

In the war zone that is the modern Internet, manually reviewing each networked system for security flaws is no longer reasonable. Operating systems, applications, and network protocols have grown so complex over the last decade that it takes a dedicated security administrator to keep even a relatively small network shielded from attack.

Each technical advance brings a snowball of security holes – a new protocol might result in a variety of implementations, which could contain exploitable programming errors. Logical errors, vendor-installed backdoors, and default configurations outbreak everything from modern operating systems to the simplest print server. Viruses seem completely domesticated compared to the highly optimized Internet worms that continuously assault every system attached to the global Internet. To combat these attacks, a network administrator needs the appropriate tools and knowledge to identify vulnerable systems and resolve their security problems before they can be exploited.

One of the most powerful tools available is the vulnerability assessment, and this chapter describes what it is, what it provides, and why it must be performed as often as possible [10].

2.2.1. BASIC CONCEPTS

Vulnerability Assessment

Vulnerability assessments are basically the process of locating and reporting vulnerabilities. They provide a way to detect and resolve security problems before someone or something can exploit them. Another common use for vulnerability assessment is the capability to validate security measures. For example, ensuring that an IDS is running as expected, determining how well this solution works.

The actual process for vulnerability identification varies between solutions. However, they all focus on a single output: the report. This report provides a snapshot of all the identified vulnerabilities on the network when it was performed, i.e. at a given time.

The ability to perform a wide security snapshot supports a number of security vulnerability and administrative processes. When a new vulnerability is discovered, the network administrator can perform an assessment, discover which systems are vulnerable, and start the patch installation process. After the fixes are in place, another assessment can be run to verify that the vulnerabilities were actually resolved. This cycle of assess, patch and re-assesses has become the standard method for many organizations to manage their security issues, as described in Figure 2 [11].

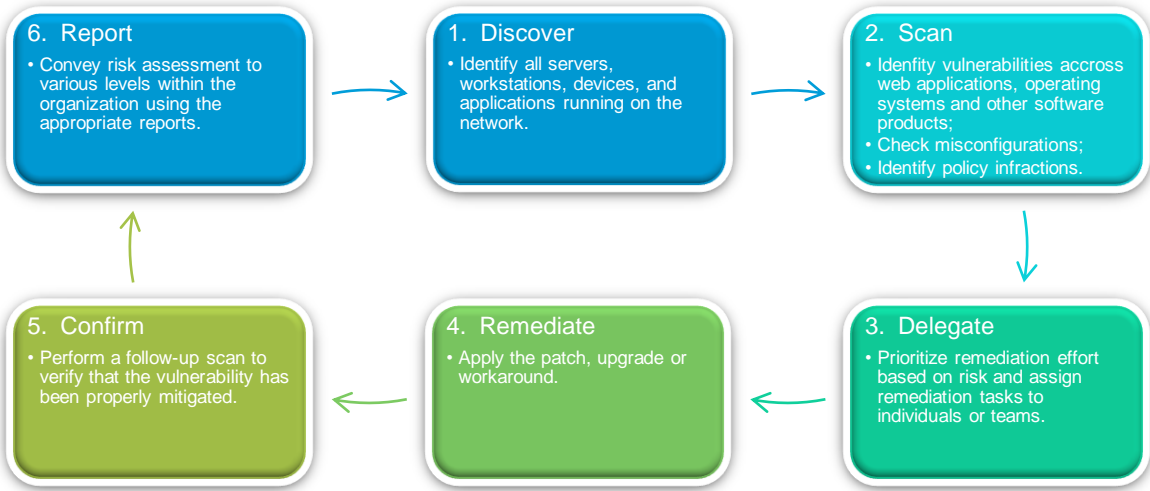

Figure 2: Security Assessment Lifecycle [11]

Many organizations have integrated vulnerability assessments into their system rollout process. For example, before a new server is installed, it first must go through a vulnerability assessment and pass. This process is especially important for organizations that use a standard build image for each system, achieving the possibility of the new server be able to be imaged, configured, and installed, without the administrator remembering to install the latest system patches.

Additionally, many vulnerabilities can only be resolved through manual configuration changes. Even an automated patch installation might not be enough to secure a newly imaged system. It's much easier and strongly recommended performing a vulnerability assessment to find these problems at build time, when configuration changes are simple and risk-free, than after the deployment of the system.

Although the primary purpose of an assessment is to detect vulnerabilities, the assessment report can also be used as an inventory of the systems on the network and the services they expose. Since enumerating hosts and services is the first part of any vulnerability assessment, regular assessments can give a current and very useful understanding of the services offered on the network. Assessments assist in crises: when a new worm is released, assessment reports are often used to generate task lists for the system administration staff, allowing them to prevent a worm outbreak before it reaches critical mass.

Asset classification is one of the most common routines for vulnerability assessment tools. For instance, knowing how many and what types of printers are in use will help resource planning. Determining how many Windows systems still need to be upgraded can be as easy as looking at the latest report. The ability to glance quickly at a document and find out what network resources might be overtaxed or underutilized can be priceless to topology planning.

Assessment tools are also capable of detecting corporate policy violations. Many tools will report P2P services, shared directories with illegally-shared copyrighted material, and unauthorized remote access tools. If a long-time system administrator leaves the company, an assessment tool can be used to detect that a backdoor was left in the firewall. If bandwidth use suddenly spikes, a vulnerability assessment can be used to locate workstations that have installed file-sharing software.

Another important use for the vulnerability assessment gathered data is event correlation. If an intrusion does occur, a recent assessment report allows the security administrator to determine how it occurred and what other assets might have been compromised. If the intruder gained access to a network consisting of unpatched web servers, it is safe to assume that he gained access to those systems as well [10].

2.2.2. VULNERABILITY ASSESSMENTS VS. INTRUSION DETECTION SYSTEMS

The difference between vulnerability assessments and IDSs is not always immediately clear. To understand the differences between these complimentary security systems, we need to understand how an IDS works.

When people speak of IDS, they are often referring to what is more specifically called a Network Intrusion Detection System (NIDS). The NIDS role is to monitor all network traffic, pick out malicious attacks from the normal data, and send out alerts when an attack is detected. This malicious activity includes DoS (Denial of Service) attacks, port scans, or even attempts to crack into computers.

Connected to a hub, network switch or tap, a NIDS works by reading all the incoming packets and trying to find suspicious patterns. If, for example, a large number of TCP connection requests to a very large number of different ports are observed, one could assume that there is someone committing a port scan at some of the network components. On the other hand, a NIDS is not limited to inspect incoming network traffic only. Often, valuable information about an ongoing intrusion can be learned from outgoing or local traffic as well. Some attacks might even be staged from the inside of the monitored network and therefore not regarded as incoming traffic at all. An example of a NIDS is Snort.

This type of defense is known as a reactive security measure, as it can only provide information after an attack has occurred. In contrast, a vulnerability assessment can provide data about a vulnerability before it is used to compromise the system, allowing security administrators to prevent the intrusion. For this reason, vulnerability assessments are considered a proactive security measure.

2.2.3. ASSESSMENT TOOLS

The first experience that many people have with vulnerability evaluation is by seeking advice from a security consulting firm to provide a network audit, accepting its wisdom. This type of audit is normally comprised of both manual and automated components. The auditors often use automated tools for much of the initial groundwork and follow it up with manual system inspection to provide careful results. Another way to obtain the same results is accomplished by simply using an automated assessment tool to perform the process in-house.

The need for automated assessment tools has resulted in a number of advanced solutions being developed. These solutions range from simple graphical user interface (GUI) software products to stand-alone appliances that are capable of being linked into massive distributed assessment architectures. Due to the overwhelming number of vulnerability tests, the commercial market is easily divided between a few well-funded independent products and literally hundreds of solutions built on vulnerability scanners such as Nessus [12], Nikto [13], or MBSA [14] from Microsoft.

Nessus

Nessus [12] is a vulnerability assessment solution that can perform many automated tests against a target network, including:

- ICMP, TCP, and UDP scanning;
- Testing of specific network services (such as Apache, MySQL, Oracle, Microsoft IIS, etc.);
- Configuration auditing;
- Asset profiling;
- Rich reporting of vulnerabilities identified.

Nessus scans can be distributed throughout an entire enterprise, inside De-Militarized Zones (DMZs), and across physically separate networks. All of the world's largest penetration testing providers and security consultants use Nessus to perform bulk network scanning and assessment.

Nessus has two components: a server (daemon), which does the scanning; and a client, which controls scans and presents the vulnerability results to the user. Nessus reporting is comprehensive in most cases. However, reports often contain a number of false positives and a lot of noise (as issues are often not reported concisely or different iterations of the same issue are reported), so it is important that consultants manually parse Nessus output, perform qualification, and produce an accurate and concise handwritten report. As with many other tools, Nessus uses Common Vulnerabilities and Exposures (CVE) references to report issues. CVE is a detailed list of common vulnerabilities maintained by the MITRE.

Nessus can be run under Linux, Solaris, Windows, Mac OS X, and other platforms. Tenable Security maintains a commercially supported and up-to-date branch of Nessus and its scanning scripts, which has enhanced features relating to SCADA testing and compliance auditing under Windows and UNIX.

Microsoft Baseline Security Analyzer (MBSA)

MBSA [14] is an easy-to-use tool that helps small and medium businesses determine their security state in accordance with Microsoft security recommendations and offers specific remediation guidance. It improves the security management process detecting common security misconfigurations and missing security updates on networked computer systems.

Built on the Windows Update Agent and Microsoft Update infrastructure, MBSA ensures consistency with other Microsoft management products including Microsoft Update (MU), Windows Server Update Services (WSUS), Systems Management Server (SMS) and Microsoft Operations Manager (MOM). Used by many leading third party security vendors including Tivoli [15], Patchlink and Citadel, MBSA on average scans over 3 million computers each week [14].

Commercial Network Scanning Tools

Commercial scanning packages are used by many network administrators and those responsible for the security of large networks. Although not cheap (with software licenses often in the magnitude of tens of thousands of dollars [2]), commercial systems are supported and maintained by the respective vendor, so vulnerability databases or further program items are kept up-to-date. With this level of professional support, a network administrator can assure the security of his network to a certain level.

Some other recognized commercial vulnerability assessment solutions consist of:

- ISS Internet Scanner [16]
- eEye Retina [17]
- QualysGuard [18]
- Matta Colossus [19]

Again, an issue with such automated vulnerability assessment packages is that they increasingly record false positive results. As with Nessus, it is often advisable to use a commercial scanner to perform an initial bulk scanning and network service assessment of a network, then fully qualify and investigate vulnerabilities by hand to produce accurate results. Matta Colossus addresses this by allowing the user to supervise a scan as it is conducted, and also to edit the final report.

2.3. MANAGEMENT

In general, network management is a service that employs a variety of tools, applications, and devices to assist human network managers in monitoring and maintaining networks. This involves a distributed database, auto polling of network devices, and high-end workstations generating real-time graphical views of network topology changes and traffic, and refers to the activities, methods, procedures, and tools that pertain to the operation, administration, maintenance, and provisioning of networked systems [20]:

- Operation deals with keeping the network (and the services that the network provides) up and running smoothly. It includes monitoring the network to spot problems as soon as possible, ideally before users are affected;
- Administration deals with keeping track of resources in the network and how they are assigned. It includes all the “housekeeping” that is necessary to keep the network under control;
- Maintenance is concerned with performing repairs and upgrades. For example, when equipment must be replaced, when a router needs a patch for an operating system image, when a new switch is added to a network. Maintenance also involves corrective and preventive measures to make the managed network run better, such as adjusting device configuration parameters;
- Provisioning is concerned with configuring resources in the network to support a given service. For example, this might include setting up the network so that a new customer can receive voice service.

2.3.1. BASIC CONCEPTS

Network Management Architecture

Most network management architectures use the same basic structure and set of relationships. End stations (managed devices), such as computer systems and other network devices, run software tools (network management agents) that enables them to send alerts when they recognize problems.

Upon receiving these alerts, management entities are programmed to react by executing a sort of actions, including operator notification, event logging, system shutdown, and automatic attempts at system repair. Management entities also can poll end stations to check the values of certain variables. Polling can be automatic or user-initiated, but agents in the managed devices respond to all polls.

Network management agents are software modules that first compile information about the managed devices in the network which they reside, then store this information in a management database, and finally provide it (proactively or reactively) to management entities within Network Management Systems (NMSs) via a network management protocol.

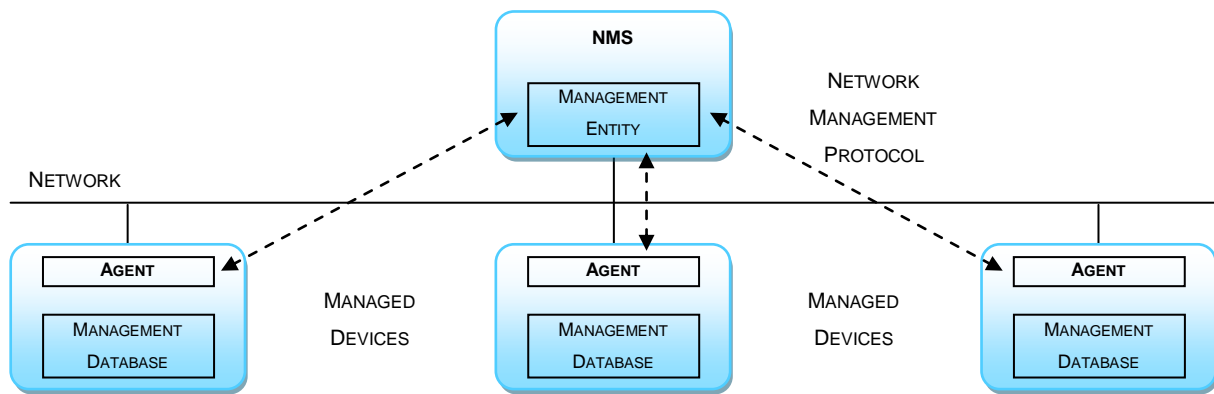

Figure 3: Basic Network Management Architecture [21]

Well-known network management protocols include the Simple Network Management Protocol (SNMP), Common Management Information Protocol (CMIP) [21], and Windows Management Instrumentation (WMI) [22]. Figure 3 represents the basic network management architecture.

2.3.2. SIMPLE NETWORK MANAGEMENT PROTOCOL (SNMP)

Networks can be monitored and controlled by using the Simple Network Management Protocol (SNMP). The network administrator usually runs an SNMP network management program, such as HP OpenView [23], to monitor servers and routers. The NMS has the capability to check the status of individual network devices.

SNMP runs on a large amount of devices and operating systems, including but not limited to [24]:

- Core network devices – routers, switches, hubs, bridges, and wireless network access points;
- Operating systems;
- Consumer broadband network devices – cable modems and DSL modems;
- Consumer electronic devices – cameras and image scanners;
- Networked office equipment – printers, copiers, and FAX machines;
- Network and systems management frameworks – network sniffers and network analyzers;
- Uninterruptible Power Supplies (UPS).

By default, SNMP provides the capability to monitor a device with notification of possible error conditions, to reconfigure limited system parameters, or to reboot or shutdown the network device.

Even though the version 3 of the protocol (SNMPv3) provides authentication, privacy and access control, SNMP has an extremely weak security mechanism [25]. As a result of not implementing encryption, SNMP versions 1 and 2c are subject to packet sniffing of the clear text password (known as community string) from the network traffic, which symbolize negative security implications.

As a result, a network auditor should be concerned about SNMP being allowed to travel unregulated across the network, forcing all SNMP managed devices to use unique passwords rather than the default ones “public” and “private” [26].

2.3.3. WINDOWS MANAGEMENT INSTRUMENTATION (WMI)

Windows Management Instrumentation (WMI) [22] is a set of extensions to the Windows Driver Model (WDM) that provides an operating system interface through which instrumented components provide information and notification. WMI is Microsoft's implementation of the Web-Based Enterprise Management (WBEM) and Common Information Model (CIM) standards from the Distributed Management Task Force (DMTF).

WMI allows scripting languages like VBScript or Windows PowerShell to manage Microsoft Windows personal computers and servers, both locally and remotely, and is preinstalled in Windows Vista, Windows Server 2003, Windows XP, Windows Me, and Windows 2000.

The purpose of WMI is to define a non-proprietary set of environment-independent specifications which allow management information to be shared between management applications. WMI prescribes enterprise management standards and related technologies that work with existing management standards, such as Desktop Management Interface (DMI) and SNMP. WMI complements these other standards by providing a uniform model. This model represents the managed environment through which management data from any source can be accessed in a common way.

2.3.4. MANAGEMENT TOOLS

Network management tools come in software suites that offer the following management functions for the general network resources:

- Graphical User Interface (GUI);
- Network topology map;
- Integration with Database Management Systems (DBMS);
- Default network resource query method;
- Event Logging.

Table 3 shows a small portion of the existing network management solutions.

Table 3: Examples of Network Management Tools

Tool	Type
HP OpenView	Network / Systems Management
IBM Tivoli NetView	Monitor Program based on SNMP Protocol
Spiceworks	Network Monitoring Software for Network Management
AutoScan Network	Network Monitoring and Management Tool
Intellipool Network Monitor	Network, Server and Performance Monitoring on SNMP enabled devices
System Center Operations Manager	Performance and Event Monitoring product from Microsoft
CA Spectrum	Network Fault Management
Multi Router Traffic Grapher	Free software for Monitoring and Measuring the Traffic Load on network links

2.4. SUMMARY

Three related and yet distinct principles that help IT departments manage their software and equipment were carefully introduced: Network Auditing, Assessment and Management.

If combined and used effectively, these methodologies contribute to assure higher levels of security on enterprise network systems, and when carefully assembled with an assortment of network scanning methods and algorithms, achieve a comprehensive network description, through efficient and accurate techniques.

3. STATE-OF-THE-ART

3.1. NETWORK DISCOVERY

Since “You can’t manage what you can’t see” [27] and as previously stated, network discovery is one of the main components considered necessary to accomplish or analyze the security state of any enterprise network.

It can be essentially described as the process to scan any network to create an accessible inventory as well as present a visual topology containing all of its active network devices and systems. Implementing a full IP address and host fingerprinting detection accurately discovers and maps:

- Gateways and hosts;
- Machine names;
- Common open ports;
- Operating systems for each host discovered;
- Private networks;
- Access points to the discovered networks.

Additionally, this identifies devices that the network administrator did not know were on the network, including hosts that may have been maliciously or accidentally placed.

To use the discovery service, the administrator generally submits a few DNS information or a set of IP address ranges to find computers within those domains or address collection [28]. Despite helping to locate devices outside the DNS record and to bypass firewall rules or router ACLs, a recurring challenge seems to arise when assessing organizations with an assorted allocation of IP addresses.

Various approaches have been described in the literature for discovering network topology. Generally, they are based on SNMP and either active probing or passive monitoring methods [29]. Additional and related terminology is evaluated as follows.

3.1.1. AUTO DISCOVERY

“Auto Discovery” is a term that defines a methodology for network discovery that will automatically and efficiently identify which network assets are alive, basing on the information available by specific network equipment (e.g. routers or gateways) or by taking advantage of particular network protocols.

SNMP

One effective way to perform an automatic discovery of network topology is by using SNMP, assuming that the protocol is available everywhere in the network. The first router added to a temporary set list is the discovery node's default gateway. For each router in the list, neighboring routers are found from that router's Routing table and hosts are obtained from its ARP table. This information helps to enlarge and improve the identified IP address list, the discovery of different connection paths, and the creation of a diagram of external links to routers, firewalls, gateways, etc.

Several approaches to finding layer-3 (IP network) topologies have been proposed [30] [31] [32]. One approach uses pattern matching on interface counters available through SNMP [33].

Although standard SNMP MIB information is widely supported in modern IP networks, requiring no modifications to the operating system software running on elements or hosts [34], recognizing the importance of layer-2 topology, a number of vendors have recently developed proprietary tools and protocols for discovering physical network connectivity. Examples of such systems include Cisco's Discovery Protocol [35] and Nortel Networks' Enterprise Network Management System [36].

Another approach finds the topology based on tables for the spanning tree algorithm available through SNMP [37], and a different algorithm shapes the concept of operational topology and a technique for discovering an IP network. The algorithm is dynamic, constantly evolving and discovering new nodes, edges and paths as they are exercised, including the usage pattern of paths between endpoints [38].

A different algorithm once more requires the installation of SNMP agents on routers, switches and network printers [39]. The ARP cache of the routers is obtained via SNMP and then an ICMP request / response mechanism is used to discover the network. This technique enables network administrators to run on the network, after installation of SNMP on routers, switches and network printers. The goal is to automatically discover network topology in an efficient manner.

There are, however, many situations where SNMP cannot be used. Despite being a well-known protocol, commonly used on enterprise network routers and switches, SNMP isn't largely used in workstations and servers. At the same time, since no network device will have an ARP or Routing entry for all the devices in the network, all other IP addresses (not acquired through SNMP) cannot be ignored. As this is true, most solutions to IP network topology discovery require SNMP to be installed on nearly all network elements for an accurate topology discovery. The problem is that, for security reasons, access to SNMP can easily be turned off by many network administrators, and enabling it can be a very time consuming task as it requires manual intervention. A remaining weakness is that, for much information a specified host owns (e.g. from ARP or Routing tables), it is stored for a short period of time and can be lost or outdated before being captured [25].

Relying on SNMP, some tools available in the market that can be used for monitoring the network and particularly for discovering the network topology include InterMapper [40], LAN Surveyor [41], SolarWinds [42], or NetworkView [43]. Also, many recognized common network management tools, such as HP OpenView [23] and IBM Tivoli [15] are based on closed proprietary SNMP technology.

Zone Transfer from a DNS Server

A Domain Name Server keeps a binding from every name in the domain to its IP address. Most DNS servers respond to a "zone transfer" command by returning a list of every name in the domain. Thus, a DNS zone transfer is useful in finding all hosts and routers within a domain. This technique has low overhead, is fast, and accurate. Nevertheless, network managers frequently disable DNS zone transfer due to security concerns [30].

3.1.2. ACTIVE PROBING

Active probing finds active network resources by mutually sending packets to them as well as analyzing its response. We present several related tools and scanning techniques, which give support to network discovery [44].

Ping Scan

Generally, every IP host is required to echo an ICMP Ping packet back to its source. The ping tool therefore should accurately indicate whether the pinged machine is active or not. With suitably small packets, ping also has a low overhead. As pings to live hosts succeed within a single round-trip time, which is a few tens of milliseconds, the tool is fast. Pings to dead or non-existent hosts, however, timeout after a conservative interval of 20 seconds, so pings to such hosts are expensive.

The Ping Scan technique consists in sending ICMP echo request packets sequentially to every IP address on the network, relying on the response of each active device with an ICMP echo reply.

The intrinsic problem is that blocking ICMP sweeps is rather easy, simply by not allowing ICMP echo requests into the network from the void. Additionally, both firewalls and IDSs can be configured to detect and therefore block sequential pings [30].

TCP / UDP Scans

As earlier acknowledged, some active network resources running network services may not react to ICMP echo requests. Given this point of view, instead of directly looking for the existence of network devices, it is possible to search for open ports, identifying public services being executed. If a response is received from a remote device, we can safely identify it as active.

Nonetheless, because results can be affected by firewalls or host countermeasures, in order to accurately identify available devices on the network, each address is supposed to be scanned by probing all target ports, with the intent to identify which services are running. In any case, it should be trustworthy to focus the discovery on a set of standard TCP or UDP service ports, 21 (FTP), 22 (SSH), 23 (Telnet), 80 (WWW), 135 (DCOM Service Control Manager), 161 (SNMP) and 445 (Microsoft Directory Services), hoping to rarely be filtered [45].

ARP Scan

Sending a chain of broadcast ARP packets to the local network segment and incrementing the destination IP address of each packet, is a first-class network discovery technique to find its active devices. Since every network equipment must answer when its IP address is mentioned on a broadcast ARP, this technique is supposed to be failure-proof. In contrast to Ping Scan, which response is optional, network elements must reply to broadcast ARP. Difficult to be blocked, this technique's downsides are that it only works for the current local subnet and is easily detected by sniffers and IDSs.

Traceroute

Traceroute discovers the route between a probe point and a destination host by sending packets with progressively increasing TTLs. On seeing a packet with a zero TTL, routers along the path send ICMP TTL-expired replies to the sender, which marks these to discover the path.

Traceroute is usually accurate because all routers are required to send the TTL-expired ICMP message. However, some network administrators are known to hide their routers from traceroute by manipulating these replies to collapse their internal topology. This reduces both the accuracy and the completeness of topologies discovered using traceroute. Two probes are sent to every router along the path, so this tool generates considerably more overhead than ping. Since probes to consecutive routers are spaced apart to minimize the instant network load, the time to complete a traceroute is also much longer than a ping.

3.1.3. SMART ACTIVE PROBING

Because of the large number of possible IP addresses, sending separate probe requests to each and every one is not feasible in determining the devices that are alive in the network. Therefore, it is important to dynamically decide the probability that a certain network address has to be alive. Stipulating that this value is considerably low, and to generate a quick initial response to the network discovery process, the device won't be initially probed.

An intelligent and efficient algorithm for generating a list of IP addresses having a high probability of being assigned to devices in the network is proposed, adding the capability to analyze its dynamic performance and amending its functionality to generate better response [39]. This algorithm has been evaluated, implemented, and extensively tested in the research labs at NUST Institute of Information Technology, Pakistan. The authors proposed an intelligent algorithm that requires installation of SNMP on the routers, switches and network printers. They retrieve the ARP cache of the routers via SNMP and then use ICMP request/response mechanism to discover the network. Figure 4 shows the comparison between the results in terms of time and number of hosts found. Figure 5 shows the comparison between the results in terms of initial accuracy.

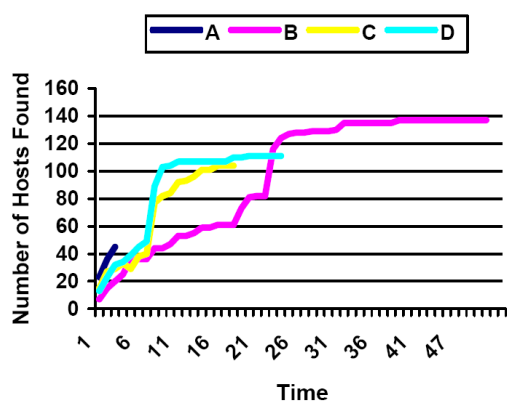

Figure 4: Comparison of Number of Hosts Found and Time Consumed [39]

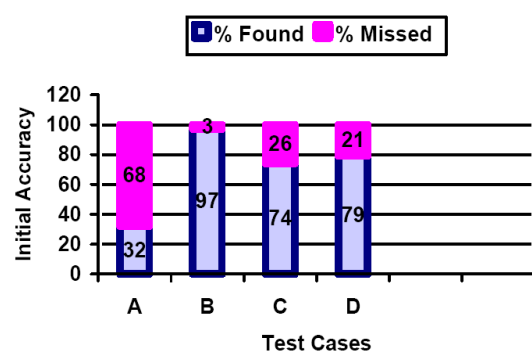

Figure 5: Comparison of Initial Accuracy [39]

The authors evaluated the tests with a different set of parameters, and describe the results as follows:

- From Figure 4 it can be seen that Test A has a very steep but short slope, giving quick initial response. The reason for such a behavior is that the intelligent algorithms have skipped a lot of IP addresses. It quickly found the hosts whose IP addresses were in sequence or grouped together, and then skipped most of the IP addresses, causing the high miss percentage. It queried a total of 901 IP addresses;
- Test B was the longest test. Initially there is a steep curve but not as steep as test A, C or D. This is because it skipped less IP addresses and the next sequence of IP addresses were not quickly reached (due to timeouts). Then in the middle stage there is a sudden rise as it found the next sequence of IP addresses. Then the slope becomes almost horizontal at the later stage because it was running for IP addresses that had not been assigned to any host. It had 97 percent initial accuracy because it skipped few IP addresses and queried about 38000 IP addresses;
- Tests C and D have quicker initial response. They maintain a good trade-off between accuracy and initial response. Tests C and D queried 7149 and 7214 IP addresses, respectively.
- Figure 5 shows that tests C and D discovered more than 70 percent of the network in about 15 minutes.

Even though the different scan parameters have not been described at this point, it's simple to perceive that intelligent algorithms to determine the IP ranges which have greater probability of being assigned an IP address are confirmed to reduce the number of queries required to discover the devices in the network, with the special characteristic that the discovery process yields a quick initial response.

Another considered approach compares two algorithms: using evenly spaced IP addresses from the IP address space as targets for probes, and a variation of the informed random address probing heuristic that randomly selects prefixes for probing, instead of using the arbitrary selection algorithm [46].

3.1.4. PASSIVE MONITORING

The discovery of network elements through Passive Monitoring primarily involves the employment of packet sniffers, special programs that capture all network traffic. These tools are useful to identify network elements that do not react to any of the previous mentioned techniques, and even to intercept confidential data such as passwords (e.g. community strings) or access codes, often valuable to the scanning process.

The natural disadvantage of this procedure is, due to fact that being passive, it fundamentally depends on the existence of network traffic through the connected devices in order to be accurate and efficient. In any case, as every address is captured, some additional work to filter external network addresses is required, which can possibly be inaccurate if the local network address range is unknown.

Finally, since even with an uninterrupted sniffing the process can take several hours or days to detect every active machine on the network, this technique should cover a complementary practice in order to discover a number of elements earlier undetected.

3.1.5. NETWORK SCANNING TOOLS

Nowadays, there are a numerous network scanning tools, each one with its own characteristics, advantages, and disadvantages. Some of these scanning methods are simple to understand and execute, while others are more complex and require some additional groundwork and configuration before the scan can begin.

Network Mapper (Nmap)

Nmap [47] is a port scanner used to scan large networks and perform low-level ICMP, TCP, and UDP analysis. It offers a number of advanced features such as service protocol and IP fingerprinting, stealth scanning and low-level network traffic filter analysis, and can be run under most operating platforms including Windows, Linux and Mac OS X. Most importantly, Nmap supports the following scanning techniques [48]:

- TCP SYN Scan;
- TCP Connect;
- FIN Scan;
- Xmas Tree Scan;
- Null Scan;
- Ping Scan;
- Version Detection;
- UDP Scan;
- IP Protocol Scan;
- ACK Scan;
- Window Scan;
- RPC Scan;
- List Scan;
- Idle Scan;
- FTP Bounce Attack.

The term “ping” was previously considered as a reference to an ICMP echo request and the corresponding ICMP echo reply. However, Nmap’s use of the word “ping” is more generic. In the Nmap world, a ping is any request that would prompt a remote station for a response.

The tool offers a wide variety of very flexible options to modify the techniques used, allowing customization on every aspect of the discovery. Consequently, to maximize the possibility of locating a device through Firewalls, Routers, IDSs or Packet Filters, the user is able to choose several options that can be combined together to an accurate network discovery. These ping scan (host discovery) alternatives are subsequently listed [48]:

- ARP Ping;
- ICMP Echo Request Ping;
- TCP ACK Ping;
- TCP SYN Ping;
- UDP Ping;
- ICMP Timestamp Ping;
- ICMP Address Mask Ping

Once a response is received from a remote device, Nmap identifies it as active on the network and begins scanning it for detailed port information.

SuperScan

SuperScan [49] is a graphical tool from Foundstone that runs on Microsoft Windows operating systems. It is very fast and can be used for enumeration, port scanning, and banner grabbing, and can produce a good HTML report. Foundstone notes that Windows XP Service Pack 2 limits access to raw ports and requires administrator privileges to run.

SolarWinds

The company SolarWinds offers many commercial applications. The SolarWinds Toolset [42] contains many useful tools for network, system, and security administrators. For SNMP scanning, the tool IP Network Browser is available in all of SolarWinds toolkit offerings and is a nice, fast SNMP scan tool. It allows the input of multiple targets as well as multiple community strings. As the scan progresses, the results are instantly updated and drill down as each host is finished.

AutoScan Network

AutoScan [50] is a free application designed to explore and to manage a network. Entire subnets can be scanned simultaneously without human intervention. The objective of the program is to list all equipments connected to the network, including a list of open ports per equipment. It consists of:

- Automatic network discovery;
- Detection of the OS, brand and model known;
- Ability to save the network state;
- A Samba share browser;
- A Nessus client.

NetSNMP

Net-SNMP [51] is a suite of applications used to implement SNMP. These tools work on most operating systems while its functionality may not be the same on each one. The tool snmpget downloads the SNMP information from a single machine, and snmpwalk traverses multiple machines.

3.2. SECURITY MANAGEMENT

As earlier acknowledged, security in computing is continually a problem both technical and social [52]:

- It's a technical problem as the large amount of hardware architectures, operating systems versions, application protocols and requirements, imply that the definition or implementation of security policies in distributed systems is difficult to realize and maintain;
- It's a social problem because the vast majority of computer system users and small domestic companies are normally not aware of the safety problems that may affect their regular activities and neither on how they should deal with them.

To complete this framework, there are several factors that contribute to poor security management processes. Most users employ COTS (Commercial off the Shelf) operating systems, which normally support the ease of use at the expense of safety. Because safety is uncomfortable, difficult to understand and configure, many users are simply not willing to adjust it, or support a system that is constantly placing obstacles. Thus, systems that are conducive to ease typically have to lighten up security policies and mechanisms to interfere as slight as possible with the typical user’s activity.

Currently there are already some attempts to automatically install and configure some security policies, which, in most cases, do not properly act in response to the system’s needs, also proving to be inadequate or excessive.

According to the SANS Institute, the average time of survival of a computer, connected to the Internet and without special protections, measured as the average time between communications of attacks and commitments, it's usually the order of a few tens of minutes [53].

An efficient and systematic examination of an information system or application is then needed to determine the adequacy of security controls, identify security deficiencies, and provide enough information to predict the effectiveness of the proposed security controls.

3.2.1. CONFIGURING VULNERABILITY SCANS

Vulnerability scanners discover only well-known vulnerabilities. Each vulnerability scanner has a database of known vulnerabilities. By default, it scans for IP addresses that will respond to a ping and then looks for the open ports on those addresses. For each port, the scan tool knows what the common services are. For each common service that runs on that port, it will start scanning for known vulnerabilities. The inherent problem is: how to properly configure a scan as such?

These tools should not run in their default state. They should always be configured based on the known variables of the network being scanned along with each target’s device type. By properly configuring these tools by means of feeding the output of tools designed for enumeration or network discovery into the scan configuration, the amount of time they take to run can be significantly reduced. For instance, turning off AIX scans for a Microsoft Windows asset will lower the number of tests required, and consequently the assessment duration.

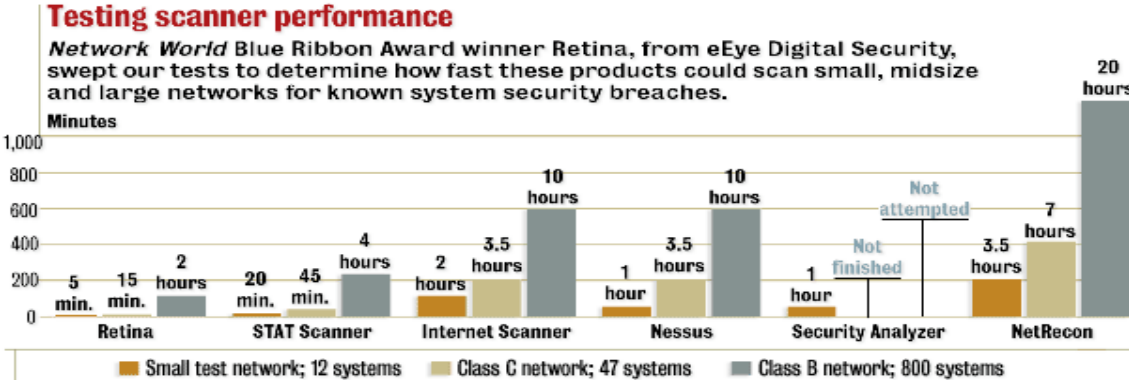

Figure 6: Vulnerability Scanners Performance Tests [54]

Figure 6 [54] presents some performance tests results conducted to six known vulnerability scanner applications. As an example, NetRecon took 20 hours to complete a vulnerability analysis to 800 network machines. Almost certainly, the test was not properly configured.

3.3. HOST DISCOVERY PROBLEMS

Different IP network scanning methods to identify live hosts allow the testing and an effective detection of vulnerable network components. Nevertheless, there are several related problems that must be solved or circumvented in the final implemented solution.

3.3.1. COUNTERMEASURES

As efficiency and accuracy are essential requirements to accomplish a practical network discovery, it's important to find all the accessible network resources through the smallest amount of time and disturbance in the infrastructure. However, there are several countermeasures to employ as considering technical modifications to networks and filtering devices to reduce the effectiveness of network scanning and probing undertaken by attackers. These protections include [2]:

- Filter inbound ICMP message types at border routers and firewalls. This forces attackers to use complete TCP port scans against all of IP addresses to map the network correctly;
- Filter all outbound ICMP type 3 “unreachable” messages at border routers and firewalls to prevent UDP port scanning and firewalking from being effective;
- Configuring Internet firewalls so that they can identify port scans and throttle the connections accordingly. However, this functionality can be abused by attackers using spoofed source addresses, resulting in DoS;
- Ensure that routing and filtering mechanisms (both firewalls and routers) can't be bypassed using specific source ports or source routing techniques;
- Ensure that firewalls aren't vulnerable to stateful circumvention attacks relating to malformed PORT and PASV commands;
- Ensure that the latest service pack is installed;
- Investigate using reverse proxy servers in the environment if a high-level of security is required. A reverse proxy will not forward fragmented or malformed packets to the target systems, so a number of low-level attacks are blocked (check Figure 7 [55]);
- Be aware of the network configuration and its publicly accessible ports by launching TCP and UDP port scans along with ICMP probes against the IP address space. It is surprising how many large companies still don't properly undertake even simple port scanning exercises.

As a result, in order to be precise, the scanner is required to intelligently utilize every possible method to discover which systems are alive, for the reason that when used independently, scanning techniques such as Ping Sweeps, TCP/UDP and ARP Scans, as well as SNMP-based algorithms, all have their own drawbacks.

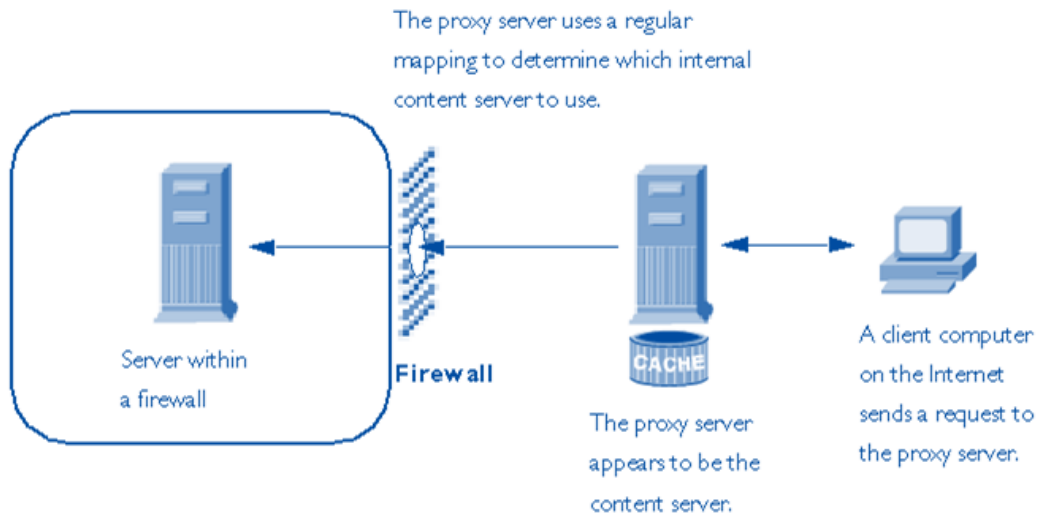

Figure 7: Reverse Proxy Server Operation [55]

3.3.2. IMMENSE ADDRESS SPACE

Some may declare that unless performing a scan on every possible IP address and port combination, the scanning isn't being thorough enough. In order to be complete, one must perform a scan as stated. Although correct, performing such a scan usually takes a considerable amount of time and is not feasible in determining which devices are alive because of the large number of possible IP addresses and port arrangements. For example, there will be more than 16 million possible addresses for Class A networks and 65,535 possible open ports for every address.

In fact, a fundamental and yet complex dilemma on the subject of network discovery is about defining and evaluating a balance between the pros and cons of every scanning technique. If being absolutely thorough, and both time and topology discovery are of no consideration, a blind scan on all IP addresses is recommended. On the contrary, in order to build an accurate and efficient network topology discovery system, not only intelligent algorithms must be applied to skip unused addresses, but also different discovery schemes should be combined.

3.3.3. INPUT INFORMATION REQUIRED

In addition to the exact administration credentials, many network scanners available on the market generally require the administrator to submit a few DNS information or a set of IP address ranges to find computers within those domains or address collection, by means of pinging that range and evaluating the answer to discover the active devices. Normally, it's possible to input an IP range (such as 192.168.113.1-10 or 192.168.1.0/24) or an IP address list (separated IP address values).

Despite helping to locate devices outside the DNS record and to bypass Firewall rules or Router ACLs, a recurring challenge seems to arise when assessing organizations with a large allocation of IP addresses. To build an innovative and automated network discovery tool, it's significant to make as few assumptions as possible about the network, adding the improvement and intention of not requiring an IP address range as input or any other privileges.

3.4. NETWORK TOPOLOGY DISCOVERY

The first step for integrating and automating related infrastructure management disciplines and processes that are loaded by disparate and incompatible tools is to gain an accurate, complete, and up-to-date picture of the network infrastructure.

In the typical organization, the complexity and dynamic nature of the distributed environment make it difficult to sustain visibility into assets and even more complex to determine their interrelationships. Manual discovery of the environment is possible, but very cumbersome, costly, and risky. Organizations require this level of discovery and need to automate the process as much as possible. In an attempt to solve the problem, many organizations have deployed automated discovery tools that have the ability to discover assets, as well as application dependency mapping products that attempt to document relationships between IT components and business services. Most tools, however, are limited in scope and reveal only a part of the total environment. To expand their view, organizations have deployed multiple tools from multiple vendors, resulting in fragmentation of data across multiple, incompatible, and often conflicting data stores.

Virtually all existing network topology discovery tools use the earlier described network management paradigm. That is, distributed agents are deployed on managed devices to collect local information and report it back to some management unit. Those that use standard protocols such as SNMP fall into this model too.

To discover network topology by taking advantage of SNMP, the algorithm is based on the information stored in the router's Routing or ARP tables: the Routing table contains information used for internet routing and can be used to derive network topology; to discover the connectivity of other hosts, a router's ARP table is used. This scheme continues in a recursive manner across the entire network.

Topology discovery via SNMP offers the benefit of interoperability among devices from different vendors, as well as efficiency and accuracy on networks that have SNMP enabled. Conversely, this is just the problem. To accurately perform a network topology discovery, we cannot assume that SNMP is globally deployed on network environment, or the community string is either predictable or known.

3.5. SUMMARY

Without full visibility of what's happening on a network, all organizations are exposed to unnecessary costs and risks. A network discovery process easily helps network managers to submit scan reports to the administration and to determine the network perimeter. It also identifies devices that the network administrator did not know were on the network, including maliciously or accidentally placed hosts, assisting the system administrators in securing their information systems. However, current proceedings rely on the fact that SNMP is universally deployed, particularly at end-systems, or that the discovery tool is allowed to have administrative privileges, also requiring much preliminary user intervention.

Vulnerability scans identify vulnerabilities, categorize the risks, and then provide solutions or recommendations. A powerful, up-to-date and easy-to-use remote security scan tool ensures that web sites, servers, routers, firewalls and other network connected devices are free of known vulnerabilities.

Nevertheless, just before running a vulnerability scan to a prearranged IP address collection, the achievement of a complete network discovery process is truly significant. This practice not only provides the vulnerability scan the proper target address collection, but also categorizes every IP enabled device, including routers, computers, switches (both managed and unmanaged) and network printers, this way managing different tests for each grouping, and consequently producing more efficient results.

These situations clearly persuade the development of effective, intelligent and general-purpose algorithmic solutions for automatically discovering the current physical topology of an IP network to assess its security state, also intending to oppose or contradict the previously acknowledged network scan countermeasures.

4. PROPOSAL

The proposed solution to the stated problems is the implementation of a genuine, intelligent and automated network discovery and vulnerability evaluation framework. The implementation is neither simple nor straightforward. Therefore, a series of successive steps must be taken in order to ensure its suitability. The suggested architecture to achieve the expected results is depicted in Figure 8.

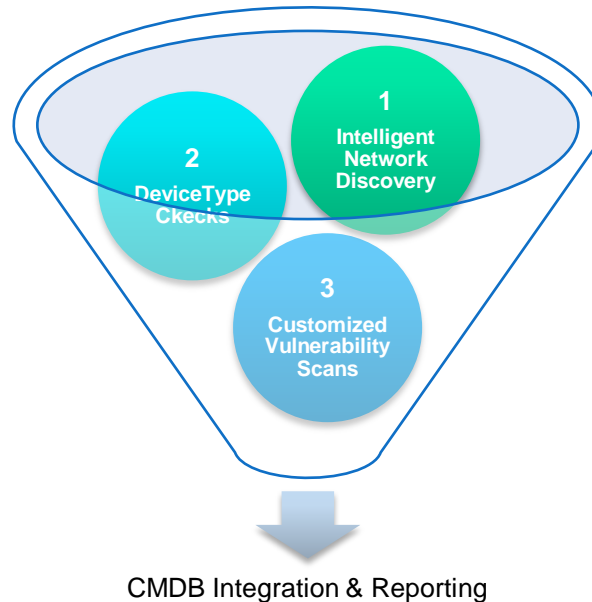

Figure 8: Proposed Framework Architecture

4.1. INTELLIGENT NETWORK DISCOVERY

For an accurate topology discovery, almost all the existing solutions require the configuration of agents on nearly all network devices, a requirement only feasible within a network management approach. In practice, additional algorithms have been designed to either perform in a predefined or predicted manner, otherwise providing evidence to be ineffective at all [25].

Integrating different host scanning techniques, applying and improving the intelligence of the existing discovery algorithms, and employing the available information from the protocols and configurations used while making as few assumptions as possible about the network, is the indispensable work to build a genuine, intelligent and automated network discovery framework.

4.1.1. EFFICIENCY & INTELLIGENCE

Nearly all corporate networks have a common and overwhelming goal. They aim to provide the maximum quality of service while maintaining the maximum amount of uptime. Thus, if the scanning method is aggressive with a low amount of latency, there's a possibility of downtime due to services crashing, systems not responding, or bandwidth exceeding the capacity of the network.

Distributed Scan

When performing a penetration testing or a commercial security auditing, one significant objective is to identify security risks without being noticed by the rest of the organization. To prevail over this issue, only the smallest possible network packets with just a couple of frames are sent into the network, as well as the infrequent opening of application sessions to ensure the art of misdirection.

As a result, by blending into the environment, nobody will ever know the scan is being processed. The distributed scan option provides this level of cover by looking at the IP address pool to be scanned and mixing them up. Most enterprise management systems poll devices in order, from highest to lowest. As Figure 9 [56] illustrates, instead of scanning through the list of IP addresses on a subnet in numerical order, the list is completely rearranged. There's no way to know which IP address will be next. Subsequently, when examining a trace file of network traffic, the proposed option makes it difficult to see a pattern, thus revealing to be merely impossible to fall into a trap.

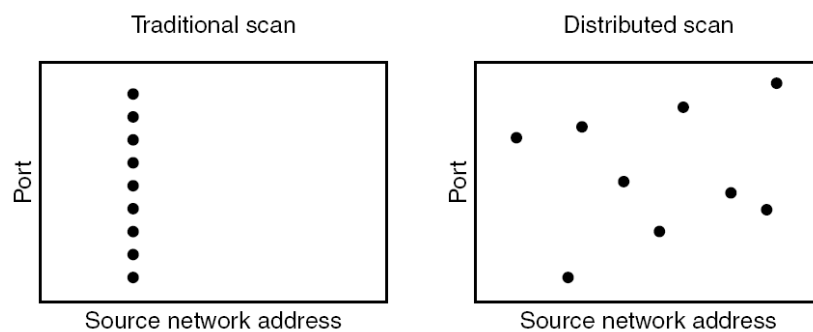

Figure 9: Traditional Scans versus Distributed Scans [56]

No Input Information Required

Our network discovery system may operate by querying only the local IP subnet to which it is attached, receive a manual list of IP addresses and IP subnets against which to operate, but most importantly and innovative, start by querying the local IP subnet to which it is connected and then query remote IP subnets after learning about their existence using assembled information from local routers or other elements on the local IP subnet.

Evidently, in order to present the most complete and efficient network coverage, the network administrator should always provide as input all the network information he knows, including accessible network credentials or community strings, host addresses, ranges, and subnet prefixes. The problem occurs when assessing organizations with a large or unknown assortment of addresses. The input information can easily ignore those devices that the administrator did not know were on the network, including maliciously or accidentally placed hosts.

Even though, the proposed approach does not force any network information at input. A preliminary inventory straightforwardly contains the entire discovery device's available information, including predictable addresses, subnet masks and ARP cache, as well as identified gateways and servers to recursively query those devices for liveliness.

Intelligent Address Miss

Sending requests to inactive hosts can waste considerable amount of time in the discovery process. We propose the implementation of an algorithm that queries hosts having higher probability of being active, leaving out a brute force evaluation of every possible IP addresses. The algorithm is self learning in the sense that it learns and decides for itself which ranges of IP addresses to send requests that yield a quick initial response. The efficiency of the algorithm is greatly improved as it analyzes its performance and automatically amends its functionality.

Because no network device will have entries of all the devices in the network, the proposed solution cannot ignore the other IP addresses. To accomplish a complete discovery, other process is responsible for querying the remaining addresses to determine their availability. This is called the Completion Phase, and runs after the algorithm has been performed.

At this point, the advantage of our proposal is that it yields a quick initial response that tries to discover the largest network segment possible (assuming efficiency) and then a complete and comprehensive discovery (guaranteeing accuracy).

4.1.2. ACCURACY

As already mentioned, to get the most recent network mapping, our solution assures that the most advanced techniques are assembled and used in order to oppose and contradict the main countermeasures system administrators can configure on the network. Therefore, in order to ensure correctness and oppose an incomplete discovery, we propose to assemble two auto discovery methods (SNMP and WMI), several active probing techniques, and a passive monitoring approach to accomplish a scan as stated.

Auto Discovery Method

A network auto discovery technique may, by itself, assure the network discovery process. The problem is the impossibility to have the guarantee that the particular protocol that permits the process will be globally available through the network.

If, for instance, no SNMP enabled device contains information about a given network segment, the process immediately turns to be inaccurate, omitting the great majority of any specific subnets or connected devices. As well, as all the network information obtained only persists for a limited period of time, the accuracy of the procedure cannot be assured on that specified moment. As this is true, the auto discovery techniques cannot be exclusively used to resolve these natural problems. Despite being the fastest technique (when globally available), other methods must also be employed to support the performing of an accurate network discovery process.

Active Probing Techniques

Active probing is a technique that uses stimuli (packets) in order to provoke a reaction from network elements. According to responses, or lack thereof, received from the queried network elements, knowledge about a network and its elements is gathered.

The information an active network discovery system attempts to collect may include the following:

- Inventory of network elements and some of their properties;
- Information on network services and their version;
- Topology related information;
- Vulnerability analysis related information.

An active network discovery system detects network elements that are operational on a network at the time of the discovery only if the packets sent are able to reach the probed elements and the probed elements answer the sent query type.

Network obstacles, such as network firewalls, host-based firewalls, load balancers, NAT devices, etc. prevent probe packets from reaching their target network elements. This results in those network devices being undiscovered and the results of the active network discovery to be incomplete.

A good example is Microsoft Windows XP SP2, where a host-based firewall is installed by default. The presence of hosts running Microsoft Windows XP SP2 having their host-based firewall enabled cannot be discovered by a simple active probing network discovery system. The trend of including a host-based firewall as part of an operating system installation is not limited to the newest Microsoft Windows operating systems, but is found as part of other operating systems, such as FreeBSD and other Linux distributions, Mac OS, and so on.

In order to assure the highest level of accuracy, various host detection techniques and network protocols must then be used hoping to prevail over these challenging countermeasures.

Passive Monitoring Approach

Theoretically, the usage of a passive network discovery system has zero impact on the performance of the monitored network. This is due to the fact that the monitored network traffic is copied and fed into the passive network discovery system. Its operation does not involve actively querying elements residing on the monitored network in order to gather information about them, about the network, or other elements. In fact, for the reason that a passive network discovery system does not send any packets to the network and does not pose a risk to the stability of a monitored network, it can hypothetically be installed on any network.

A passive network discovery system is able to detect active network elements, which operate behind network “obstacles” such as firewalls, and send or receive network traffic over the monitored network. The information collected by these systems might be used for the following purposes:

- Building the Layer 3 based topology of a monitored network;
- Auditing;
- Providing network utilization information;
- Performing network forensics;
- Performing vulnerability discovery;
- Creating a context regarding the network operation;
- Feeding information collected from a monitored network into other security and/or network management systems in order to enhance their operation by allowing them to have some context regarding the network they operate in (information about the network, such as SNMP community strings, or additional properties).

4.1.3. SMART TOPOLOGY DISCOVERY

Network management protocols should be used to carry out an efficient and hopefully accurate network topology discovery. As earlier stated, because these protocols are not assured to perform complete network coverage, other methods must be proposed to complement the former.

A customized Traceroute tool is proposed to bypass gateways that block traditional traceroute packets or further specified protocols. It provides the functionality of the standard traceroute utility and allows the trace to be performed over any port.

We propose three different protocols to perform a custom trace over the network: ICMP (the default method the Internet Protocols suggest to do a trace), UDP and TCP [57]. Normally an ICMP trace will do the work. But it is possible that ICMP does not show the real picture: routers can use different priorities or security measures for different types of traffic. So a UDP or a TCP trace can reveal a more realistic picture.

Another proposed intelligent approach that improves efficiency is the trace path predictability. At the same time as the physical network topology begins to come together, it is possible to guess the gateway of several active IP addresses. If, for instance, the host 10.0.1.53 has 10.0.1.254 as its gateway, we can confidently predict that all the hosts from 10.0.1.54 to 10.0.1.253 will also have the same gateway. In consequence, this process' duration is clearly improved.

4.2. DEVICE TYPE CHECKS

After acquiring the status of all network assets, their types may be determined. This process should use a Port Scanning and Operating System Detection engines to every IP address resolved, determining its device type (i.e. gateway, host, etc.) and port status. Depending on the device type of the given address, another procedure will be responsible for running a variety of security and vulnerability tests.

4.2.1. PORT SCANNING

This process is designed to search a network host for open ports. This is often used by administrators to check the security of their networks and by hackers to compromise it.

While some port scanners only scan the most common or most commonly vulnerable port numbers on a given host, the result of a scan on a port is usually generalized into one of three categories [58]:

- Open or Accepted – The host sent a reply indicating that a service is listening on the port;
- Closed or Denied or Not Listening – The host sent a reply indicating that connections will be denied to the port;
- Filtered, Dropped or Blocked – There was no reply from the host.

Based on this report, open ports may well present two vulnerabilities of which administrators must be wary – security and stability concerns associated with the program responsible for delivering the service, or the operating system that is running on the host. Even as closed ports only present the latter of the two vulnerabilities that open ports do, blocked ports do not present any reasonable ones.

4.2.2. OS DETECTION / FINGERPRINTING

This process is not a port scan, although it generally works in conjunction with the scanning processes [48]. The fingerprinting is based on the remote device's responses when sent a group of very specific packets. There will be subtle differences in the responses received from different operating systems under certain circumstances.

If a particular operating system receives a TCP ACK frame to a closed port, it may react differently than other operating systems receiving the same frame. It's these minor response variations that allow detailed "fingerprints" for different operating systems and devices. The process can, as well, automatically skip tests to closed ports and use some original logic to decide how many retries to attempt when an answer isn't received.

Auto configuring the vulnerability scan by means of device type checks that distinguish its operating system, different tests for each grouping can be managed therefore producing more efficient results.

4.3. CUSTOMIZED VULNERABILITY SCANNER

We propose to extend our network security scanning suite with robust vulnerability scanners well suited for large enterprise networks. An important requirement is making the impact of scans on network load to be as insignificant as possible. As stated above, the scanning engine is previously configured to test only those exploits that match the configuration of the network device. To assure efficiency, our vulnerability scanner will not test Windows vulnerabilities on a Linux machine, for instance.

The proposed scanning engine references a continuously updated vulnerability knowledgebase that includes all the well-known network vulnerabilities [59]. The knowledgebase is considered to be the backbone for a “hacker’s perspective”, scanning networks, systems, applications, commercial and open source operating systems. As vulnerabilities emerge – an average of 25 each week [28] – signatures should be able to be created and immediately installed in the knowledgebase, ensuring that users are always testing for the latest vulnerabilities.

Through its nonintrusive and modern scanning techniques, our proposed approach will help network administrators secure their networks, comply with industry or governmental regulations pertaining to security and privacy, and achieve peace of mind.

4.4. CMDB INTEGRATION

A Configuration Management Database (CMDB) is a repository of information related to all the components of an information system [60]. Although repositories similar to CMDBs have been used by IT departments for many years, the term CMDB stems from the IT Infrastructure Library (ITIL). In the ITIL context, a CMDB represents the authorized configuration of the significant components of the IT environment.

A CMDB helps an organization understand the relationships between its components and track their configuration. The CMDB is a fundamental component of the ITIL framework’s Configuration Management process. CMDB implementations often involve federation, the inclusion of data into the CMDB from other sources, such as Asset Management, in such a way that the source of the data retains control of the data [61].

4.4.1. INTEGRATION IMPORTANCE

IT organizations that want to achieve the full business value from Service Management initiatives need consistent, current, accurate, and secure information. That’s why a CMDB can help them manage their infrastructure more effectively. A well configured CMDB can easily monitor Configuration Items (CIs) – their location, status, and relationships to each other – and consolidate unrelated data sets. It can provide a single source of accurate information about data in the IT environment, network assets in this case. This heightened level of control is what drives IT staff to implement CMDBs, strengthening the value of the services they provide to the business.

A CMDB should work in synchronization with ITIL’s best practices for Service Management. The ITIL standards for Service Management include Service Support and Service Delivery disciplines, which depend on the process integration and control provided by the CMDB. Any IT organization concerned about the evolution and maturity of its IT processes need to understand how a CMDB enhances Service Management objectives.

This way, combining the power of a CMDB with ITIL’s best practices will assure that any organization achieves more effective and consistent management across all IT services.

4.4.2. AUTOMATED ASSET MANAGEMENT

Asset Management contributes to ITIL processes by supporting the identification, status and verification aspects. If the discovery procedure is not automated, the configuration database will rarely contain sufficiently accurate information and it is highly unlikely that the data will be the latest.

In a real-life environment, manual entry of configuration data confirms to be unreliable. Populating the configuration database with the output from automated inventory management software, the system will provide a regular update on the status of all devices on the network. This means the auditor will automatically have the information required to evaluate problems efficiently.

4.4.3. IT ASSET MANAGER FROM OUTSYSTEMS

An easy-to-use IT asset management application that automates the inventory of users, all hardware, software and security updates, providing notifications for low disk space, offline servers, unlicensed or forbidden applications, and even consents to schedule every assessment, is also attractive to incorporate into the proposed network discovery and security suite.

Since security updates prevent serious threats to any network, it may be dangerous not having them installed everywhere. OutSystems IT Asset Manager [62] helps to quickly check whether a specific update has already been installed in all computers. The biggest advantage is that the proposed IT Asset Manager solution is built using OutSystems Express Edition, meaning it can be easily customized to fit the specific needs of any company.

As ITIL has become a standard set of best practices for IT Management, the existing tools that should support used to be too rigid, too complex, and too expensive. In most IT asset management applications, users and software are tracked individually. OutSystems IT Asset Manager takes the ITIL CMDB approach, and besides listing all assets, it also presents the relationships between them.

In its present condition, OutSystems IT Asset Manager's discovery technique attempts to identify all hardware and software assets with no need to install any special agent software on remote machines. The application uses the WMI technology to introspect the entire network, and for each computer found, the application displays which applications and updates are present and when they were installed.

In any case, as there is no guarantee that a technology such as WMI is globally accessible on the network, and since accuracy is one of our main requirements, we propose extending IT Asset Manager to also include all the previously presented practices, technologies and algorithms.

4.5. REPORTING

The proposed framework should also deliver both technical data and summary data reports that summarize the security status of the network and each particular device, including specific network topology and host information, in addition to a list of detected vulnerabilities and open ports.

These reports present comprehensive network discovery scan statistics, their duration and technologies employed, a description of each security risk detected, threat severity, potential consequences of exposure, regulatory compliance information and links to validated patches and fixes. Armed with this information, security managers can prioritize where and how to take corrective action.

The OutSystems platform offers an important advance to present and manipulate these reports by completely re-engineering the process of developing, deploying, and maintaining enterprise applications. Additionally, by combining the productivity offered by visual modeling tools with the level of extensibility and customization found in integration suites or custom development frameworks, OutSystems helps a diverse range of businesses deliver their applications in weeks, instead of months or years. These advantages can clearly be applied to our proposal. For instance, at any time it is possible to export a list of all assets to MS Excel, consenting information manipulation to either create more complex reports or archive snapshots of the network state.

4.6. SUMMARY

Under this project, it's essential to develop a framework that enables both topology discovery and the identification of all of a computer network's assets on which there is no information given. Additionally, through a series of probes and tests, the framework is wanted to draw and describe, with the best possible accuracy, communication infrastructures, existing systems, applications, and vulnerabilities.

The solution must be open and flexible to enable the integration of new probes and tests, as well as additionally provide a graphical interface to allow the observation, in different levels of detail, the discovered components and associations between them.

Following what was assumed in section 1.7., our goal is to make use of the best qualities of every type of tool, while adding some intelligence to what currently exists, in order to cumulatively build a novel and innovative vulnerability assessment framework that embraces all the proposed requirements. Hence, a new approach to build an intelligent framework to automate the network topology and security state has been proposed, not assuming any protocol to be globally available or that the discovery tool is allowed to have administrative privileges, along with requiring the slightest user intervention. Our discovery includes routers, computers, switches (both managed and unmanaged), network printers and all other IP enabled devices. Moreover, our algorithms similarly impose the least possible overhead on the network, take the least possible time to complete the job, and discover the entire topology not making any mistakes.

Adding together the device type checks and vulnerability scanner functionalities makes this network security assessment suite a novel and intelligent approach that assures both efficiency and accuracy during the process. To extend the discovered network information, the framework has a peripheral layer, incorporating this information into an existing database or external CMDB, supporting IT management according to ITIL.

5. IMPLEMENTATION

5.1. ARCHITECTURE

As Figure 10 suggests, the framework contains four main layers: the Initialization Layer, the Discovery Layer, the Assessment Layer and the Integration Layer. Their purpose and relations are discussed on the following sections.

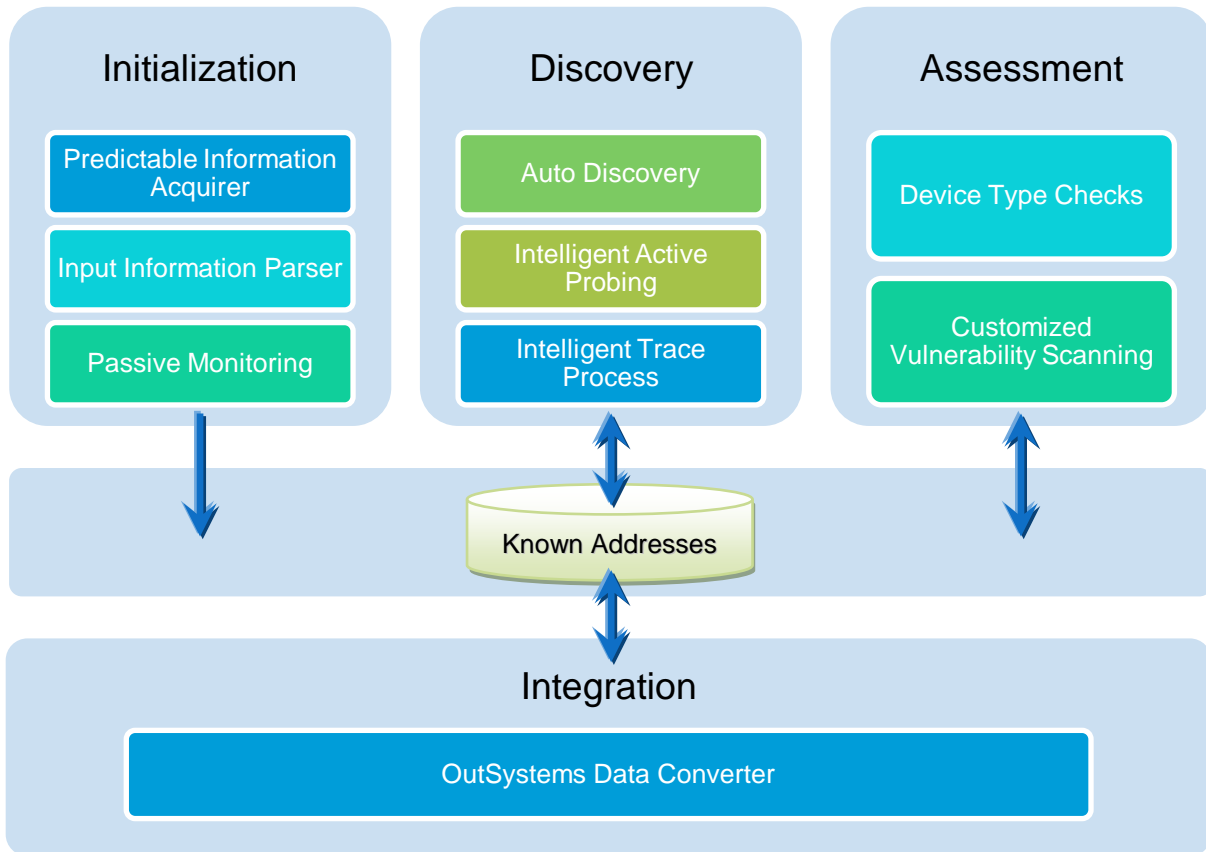

Figure 10: Implemented Framework Architecture

5.1.1. INITIALIZATION LAYER

The Initialization Layer is responsible for generating and providing a starting host address list to the discovery engine. This preliminary inventory contains all the available Network Management System (NMS) information, including its IP and MAC addresses, its subnet mask and ARP Cache, as well as all identified gateways and DHCP servers' IP addresses. This information is added to the "Known Addresses" directory.

Depending on the "Passive Monitoring" user input option, the framework takes advantage of Ettercap [63], ARP Poisoning the default gateway and manipulating the ARP table of every device on the given subnet. Now turning into reactive state and sniffing network traffic to acquire source and destination local IP addresses, this process' time limit is a user input parameter as well.

Ettercap integration consents to capture the device's IP and MAC addresses, its type and network interface card manufacturer, as well as deducing its operating system. Most importantly, Ettercap is able to intercept, for later use, clear text SNMP community strings on the captured network traffic.

Again, depending on the "Auto Discovery" user option, or if some community string has been captured through "Passive Monitoring", the framework executes preliminary parallel SNMP queries to all the identified gateways and DHCP servers for their ARP and Routing tables, using either the given community string as input, the default ones (e.g. "public" or "private"), or the intercepted ones, when appropriate. Because the Routing table contains every known network prefixes and the gateway that leads to each subnet, these and the IP addresses acquired from the device's ARP table are both added to the address directory. The process recursively continues until no new data is acquired.

Yet optional, another way to provide the Discovery Layer a starting host address list is to receive a text file as input, manually containing the "Known Addresses" list for the Discovery Layer, or an IP address range.

5.1.2. DISCOVERY LAYER

As the current list may not contain entries of all the devices in the network, the Discovery Layer intelligently takes decision on which IP ranges to query. We implemented and efficiently modified a self learning algorithm [39] to query only those devices that have higher probability of existence, as querying the devices that are not available can waste considerable amount of time in the discovery process, this way assuring a quick initial response.

If the local network address range is unknown, and since it can possibly be inaccurate, every IP address is validated according to the private IP address list: 10.0.0.0/8; 172.16.0.0/12; 192.168.0.0/16 [64]. All other are discarded if not specified as input.

The Intelligent Active Probing process is responsible for checking the status of a device. For host discovery, the framework uses Nmap's Host Discovery Module. Nmap was chosen to conduct the process since it offers a wide variety of very flexible options to modify the techniques used, allowing customization on every aspect of the discovery to maximize the possibility of locating devices bypassing IPSs and Firewalls, and undetected by IDSs, IPSs or Stateful Firewalls. The user is able to choose several options that can be combined together: ARP Ping; ICMP Echo Request Ping; TCP ACK Ping; TCP SYN Ping; UDP Ping; ICMP Timestamp Ping; ICMP Address Mask Ping.

Now diverging from SNMP and Ping sweeps, to exploit Nmap's automated functionality, the selected intelligent active probing algorithm has efficiently been modified. As Nmap can simultaneously probe several IP addresses, instead of launching the application to probe each IP address, Nmap is called once per subnet prefix, using as input a text file automatically generated by our engine.

To determine the list of gateways and subnets also including some intelligence even with the absence of SNMP, the custom and fast previously proposed topology discovery functionality has been implemented.

At the same time as the physical network topology begins to come together, every active IP address that we cannot predict its gateway has to be traced. The tools FTrace and TraceTCP were included in our proposed framework.

At this stage, we have a repository that contains several addresses that are alive on the network and some additional information describing each host. For every identified gateway, and only if the “Auto Discovery” option is scheduled, this technique is once again initiated. There will be parallel SNMP queries to each and every recognized gateway, trying to acquire their ARP and Routing tables. This process recursively continues until no new gateway is discovered or no information is returned.

5.1.3. ASSESSMENT LAYER

After acquiring the status of all devices and updating the address directory, their device types, operating systems, vulnerabilities, and other relevant information may be determined.

An accomplished benefit is that this layer is extensible to an assortment of other applications. On our approach, we integrated the framework with Nessus and MBSA, always focusing on an automated integration procedure whose configuration is imperceptible to the user, analyzing and synthesizing the results to generate a common output.

5.1.4. INTEGRATION LAYER

This layer is responsible for the conversion of all the obtained data to the specified entities in OutSystems Platform and the effective integration of this novel information with OutSystems IT Asset Manager, therefore updating the existing database.

5.2. WORKFLOW

Figure 11 presents the conceptual host discovery workflow, considering all the possible paths, including the NMS’s Predictable Information Acquirer, the Passive Monitoring option, as well as the Auto Discovery, Intelligent Active Probing, and Smart Topology Discovery recursive process.

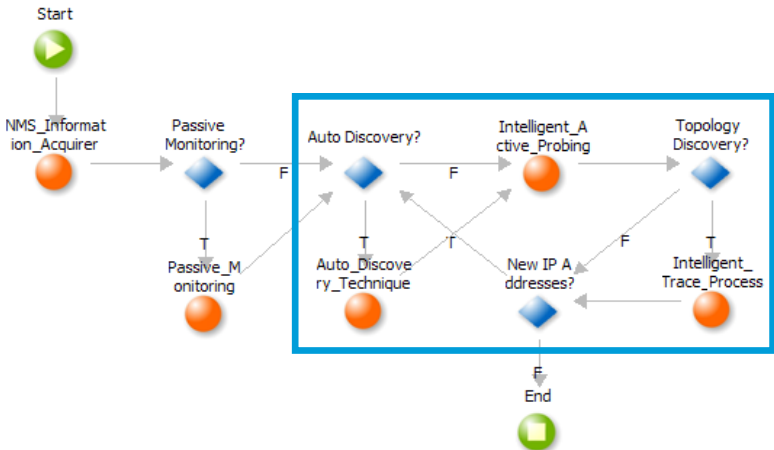

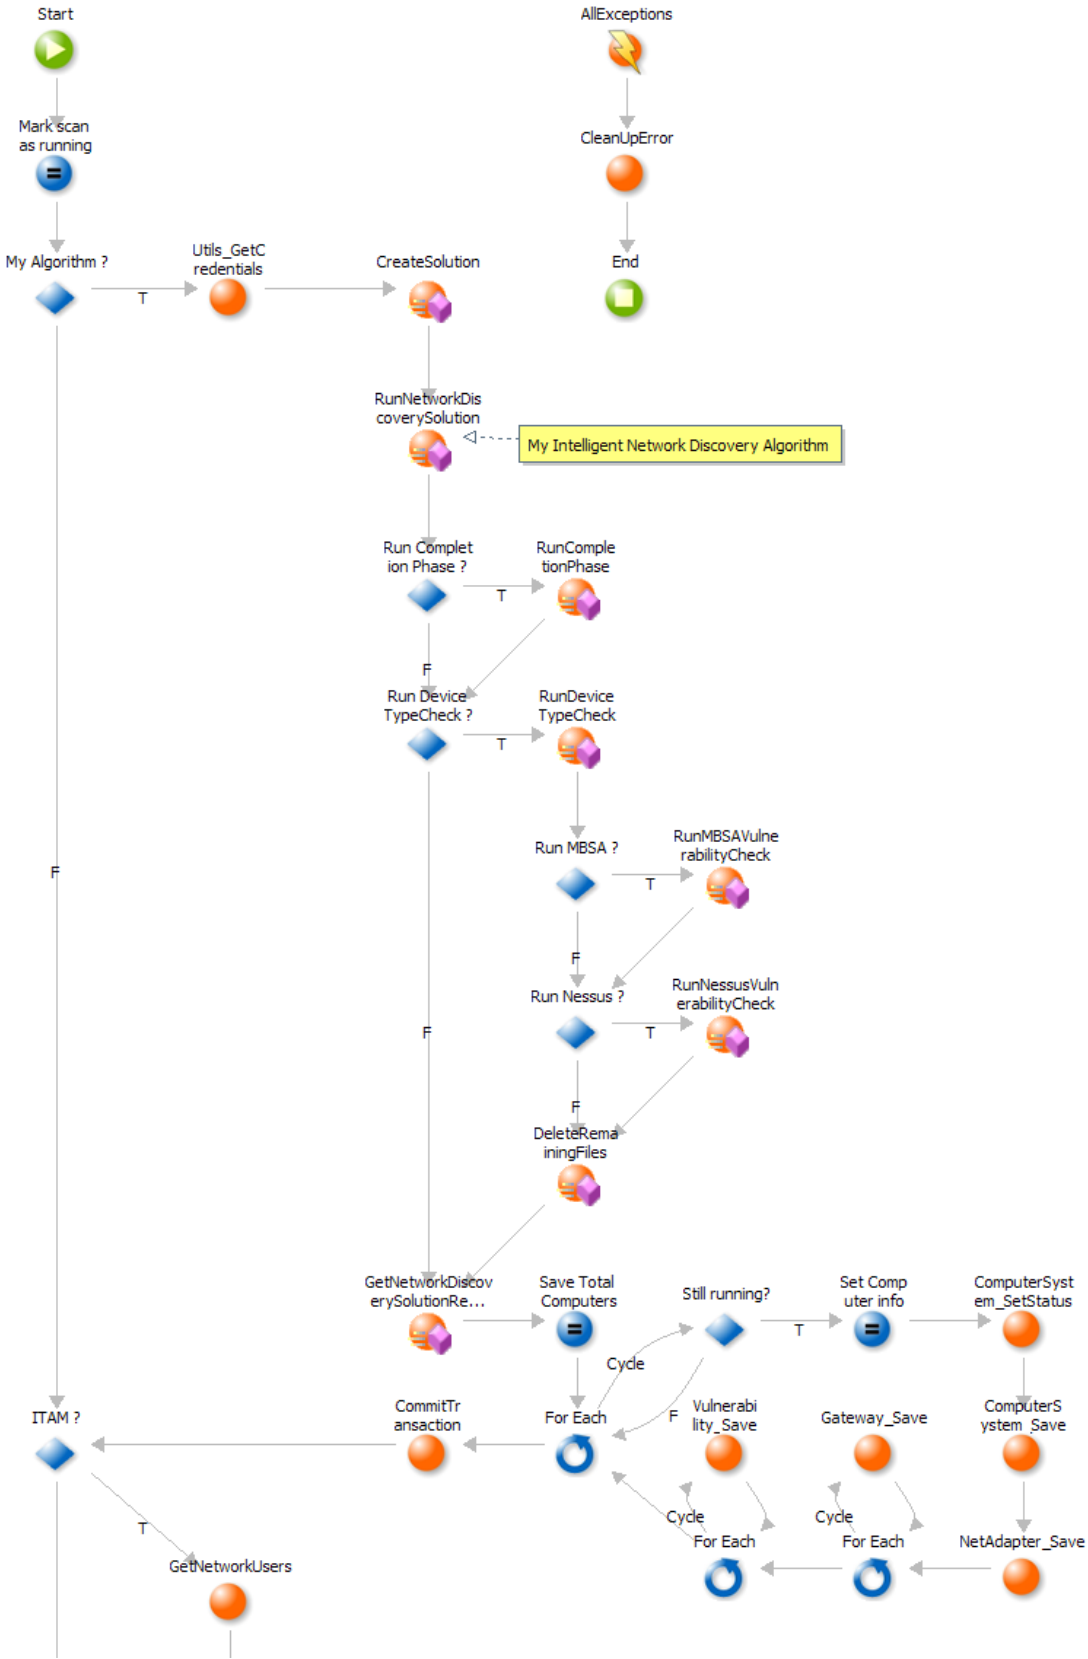

Figure 11: Host Discovery Conceptual Workflow

The actual workflow, which encloses the complete framework and includes the incorporation of OutSystems IT Asset Manager, is illustrated in Figure 12 (which continues in the next page) and is subsequently explained.

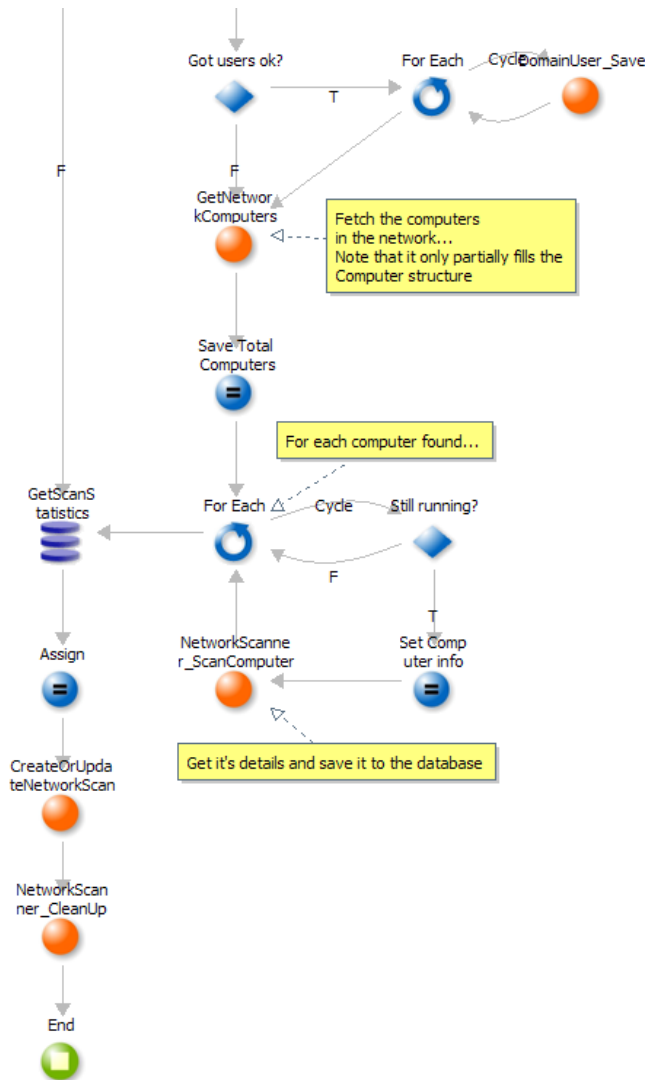

Figure 12: Complete Framework Workflow

If the user specified the newly implemented algorithm to run, the intelligent host discovery is the first step to be performed. After the possible run of the completion phase, the device type checks can also be executed. In this case, the vulnerability scanners currently integrated on the framework can also be performed. Following these scans, all the captured information is recursively traced to update the database.

Finally, the standard OutSystems IT Asset Manager is able to be performed, which captures every user and computer over the network, and saves this information to the database. This discovery can only be performed if the proper administration credentials have been provided as input, and if WMI is globally allowed and available on the network.

5.3. DOMAIN MODEL

Figure 13 presents the domain model of the proposed framework, describing the various entities involved and their relationships.

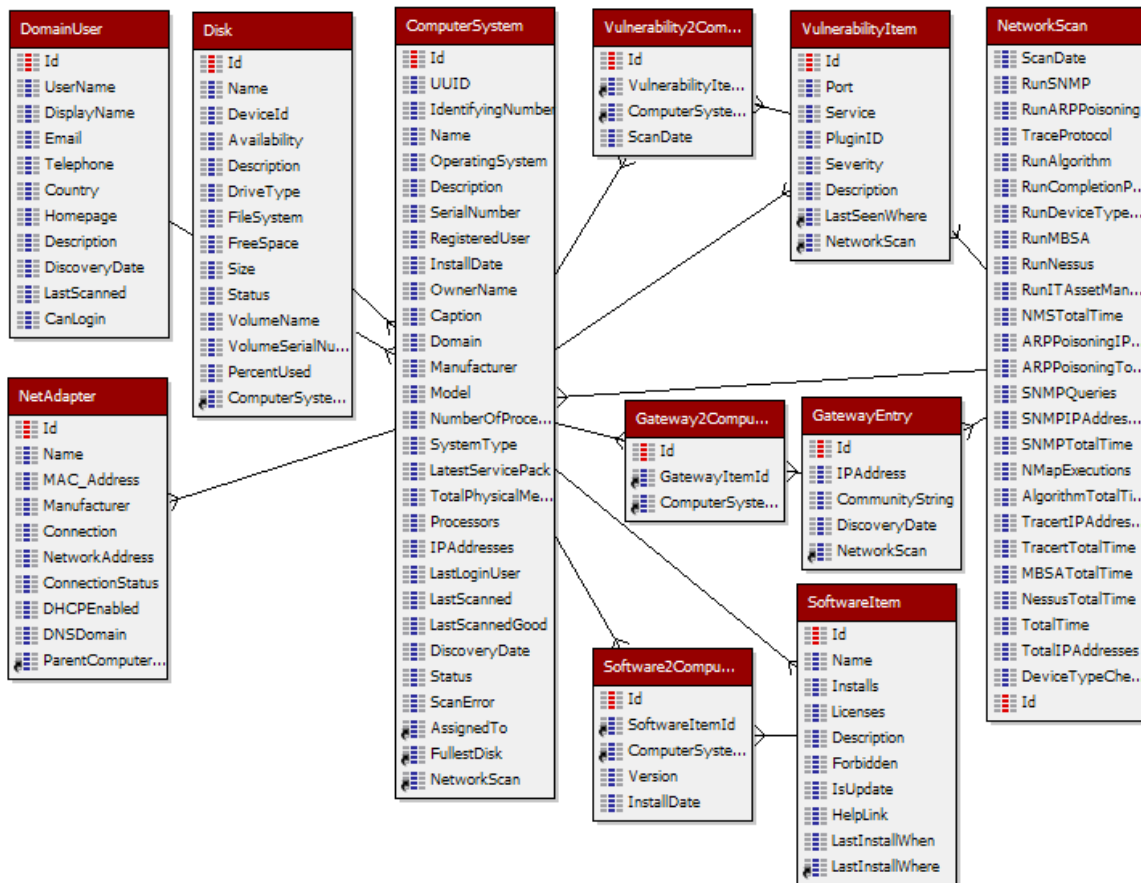

Figure 13: Domain Model

5.4. INTELLIGENT ALGORITHM FOR NETWORK TOPOLOGY DISCOVERY

Sending echo requests to all the possible IP addresses is not feasible in determining the devices that are alive in the network because of the large number of possible IP addresses. The implemented intelligent algorithm for generating a list of IP addresses having a high probability of being assigned to devices in the network [39] was efficiently modified.

As explained in the Initialization Layer section (5.1.1.), a list of the IP addresses in the ARP Cache of the NMS and its default gateway are retrieved. Suppose IP addresses 10.10.25.125 and 10.10.15.64 are obtained. A list is prepared by combining the previous list containing ARP cache of the NMS and its gateway along with the NMS IP address. For each IP address the Fourth Octet Discovery (FOD) algorithm is executed, which creates and sends echo requests to the first high priority IP address list. Afterwards, if the user specified this option, the Third Octet Expedious Analysis (TOEA) algorithm executes for a range of IP addresses and sends echo requests to the second high priority IP address list.

5.4.1. FOD ALGORITHM

First, an echo request is sent to the IP address acquired from the list, say 10.10.25.125. Then, it enters a loop, and each time it generates two new IP addresses it sends an echo request to both. These IP addresses are formed by first adding and then subtracting 1 to the last octet (i.e. 10.10.25.126 and 10.10.25.124 are formed). The addition continues until the value of last octet is less than 255 and the subtraction continues until the value of last octet is greater or equal to 1.

Two counters store the number of consecutive failures while adding and subtracting respectively. If the counter for addition exceeds a certain limit “L”, then the algorithm will skip “Sa” number of IP addresses. If the counter for subtraction exceeds “L”, then the algorithm will skip “Ss” number of IP addresses. “Sa” is formed by the multiplication of a certain number “X” and “Na”, where “Na” is a number that starts from 1 and is incremented each time the limit “L” is reached. The same process is in use for subtraction, this case with “Ss” and “Ns”.

Suppose “X” is set to 20 and “L” is set to 10, and echo requests are sent to IP addresses from 10.10.25.124 to 10.10.25.114. While subtracting, all resulted in failures (i.e. the counter for subtraction reached the limit). Then, the algorithm will skip $20 * 1 = 20$ IP addresses and will move to 10.10.25.94, and the counter for subtraction will again be set to 0. After the next 10 consecutive failures (say from 10.10.25.94 to 10.10.25.84), the algorithm will skip $20 * 2 = 40$ IP addresses and move to 10.10.25.44. Same is the procedure for addition. At any moment, if the echo request results in a success, then “Na” or “Ns” will be set to 1, and the respective counter to 0.

5.4.2. TOEA ALGORITHM

This algorithm will generate a range of IP addresses based on the IP addresses that were retrieved from the final list and after the FOD algorithm is executed. The third octet of each IP address is replaced by firstly adding and then subtracting 1 to itself. The fourth octet will be replaced with 1 (i.e. we will get 10.10.24.1 and 10.10.26.1 from 10.10.25.125). There are 254 possible values in the last octet and sending echo request to all 254 possible values is extremely inefficient, particularly if no device has been assigned an IP from this range.

The algorithm will divide the 254 values into “D” segments and will send echo requests to only the first “F” IP addresses of each segment. For example, the last octet can be divided into 8 segments, and only the first 10 IP addresses of each segment will be sent echo requests. Hence, the number of requests is reduced to 80 instead of 254. If, at any stage, a host sends an echo reply, the FOD algorithm starts execution on that particular IP address (i.e. say TOEA was executing for 10.10.26.1, and during the process 10.10.26.65 replied the echo request, then FOD algorithm will start execution on 10.10.26.65).

Redundancy checks are present to ensure that no IP address is sent echo requests more than once.

Finally, the algorithm keeps adding and subtracting 1 to the third octet until there are “C” consecutive failures (i.e. if “C” = 3 and TOEA algorithm fails for 10.10.26.1, 10.10.27.1 and 10.10.28.1, then we stop adding or subtracting 1 to third octet).

5.4.3. VARIABLES “X”, “L”, “D” AND “F”

If “L” is set to a large value, more IP addresses will be sent echo requests, resulting in a lower missing percentage, but a slower initial response. Smaller value of “X” means a smaller value of “S”. Therefore, less IP addresses will be skipped. This will also result in a lower missing percentage, but a slower initial response. Similarly, large values of “D” and “F” mean extra area covered while probing the third octet, again resulting in lower missing percentage. Smaller value of “L” and larger value of “X” means a quicker initial response, but higher missing percentage, resulting in more work in completion phase.

There is a tradeoff between initial probing accuracy and required initial response, and the values of these variables can be set according to the environment. Discovery of large networks can consume enormous amounts of time, so the values of these variables should be set as such that there is a good tradeoff between required initial accuracy and the required initial response.

The algorithm supports the heuristic that network administrators, given an assortment of IP addresses, assign IP addresses to devices in such a way that they are grouped together and in a sequence. If IP addresses assignment is done in this fashion, then the algorithm is very efficient.

5.4.4. COMPLETION PHASE

After the FOD and TOEA algorithms have executed and the two high priority lists have been queried, all remaining possible IP addresses [64] (specified in section 5.1.2.) will be sent echo requests so that the IP addresses missed by FOD and TOEA algorithms can be verified and result in a complete discovery. This is called the Completion Phase.

Thus, the algorithm can analyze its performance and through self-learning it avoids sending unnecessary echo requests. This yields a quick initial response and then a complete and comprehensive discovery.

5.5. DEVELOPMENT PROCESS

Figure 14 shows the project’s development workflow. The project was initiated in October 2007, and the list of requirements was completed at kick off. The state-of-the-art research, including current methods and applications available as well as the identification of innovative features and ideas to apply, were all fulfilled by the beginning of November 2007. During this month and until December of the same year, not only the framework architecture was completed, but there also was the evaluation of the promising development platforms and programming languages.

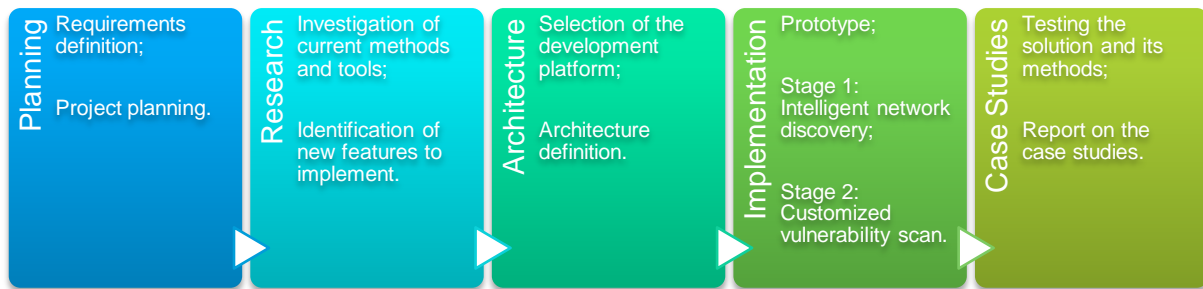

Figure 14: Project Planning

The implementation was separated in two stages: the intelligent network discovery and the customized vulnerability assessment. The first, as the foremost stage, took about two months to conclude since it's exactly the main and most innovative purpose of the current MSc Thesis. The second, which is by no means a less important phase (but the smartness of the vulnerability assessment is simply a less significant functionality to this work), took about one month to finish.

The prototype of the network discovery module was complete by the very beginning of January 2008. It included all the earlier proposed network discovery techniques, but had a visibly objectionable interface (check Figure 15).

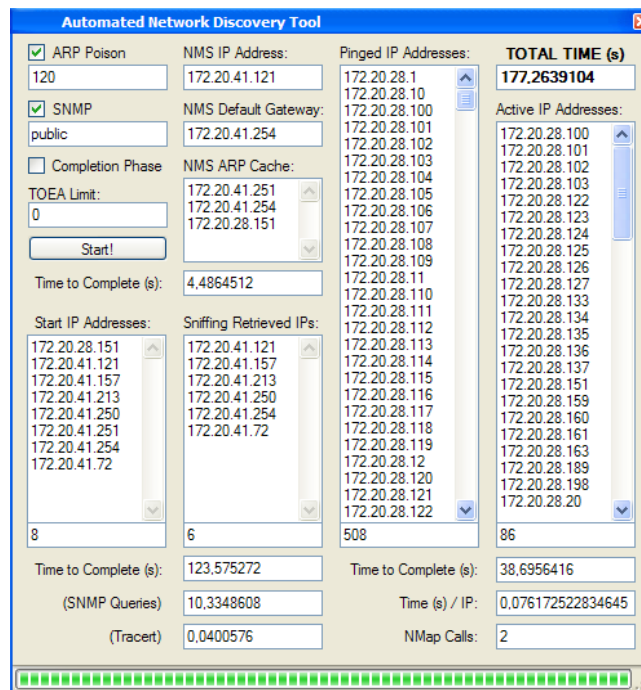

Figure 15: Prototype's Interface

Adding the three months of the implementation phase, the Case Studies began in April and ended in June 2008. This period allowed to test and maintenance the framework, and the correctness of several small bugs.

5.6. GRAPHICAL INTERFACE

As revealed on Figure 16, the result was a centralized web-based application with access control.

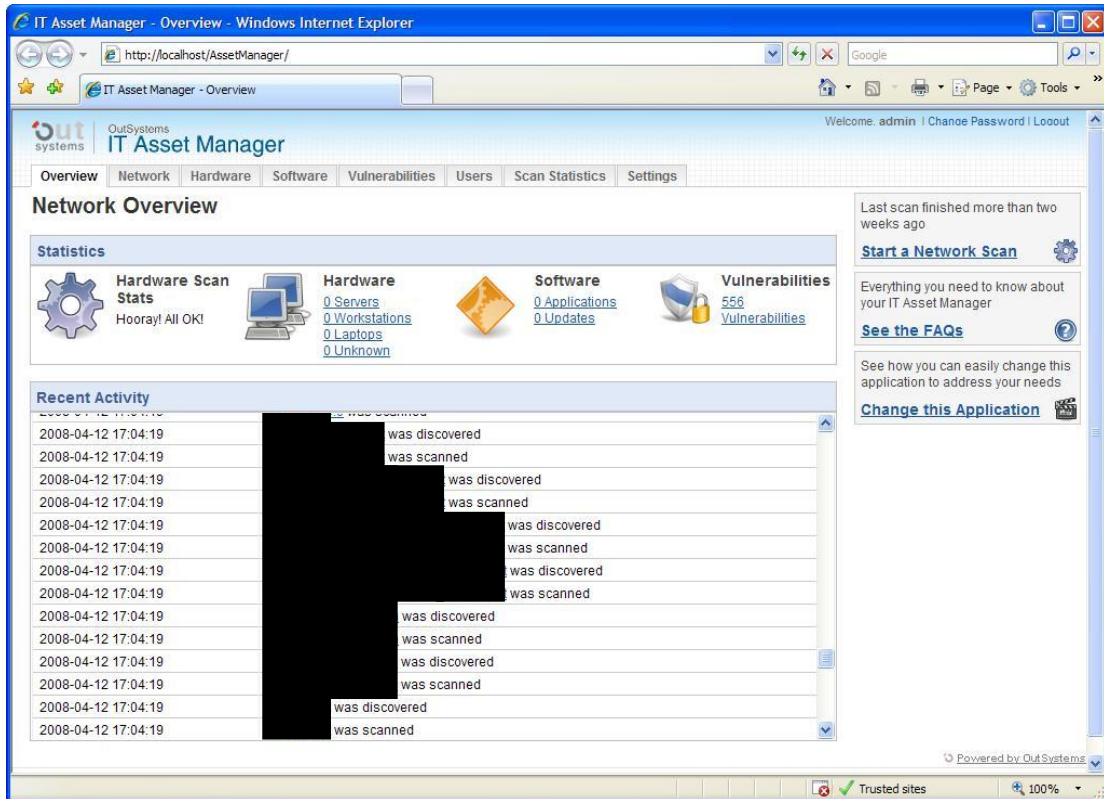

Figure 16: Network Scan Overview

On Figure 17 is a portion of the identified vulnerabilities and an example of a vulnerability, which, with a higher level of detail, presents a list of the network devices that also hold that particular exposure.

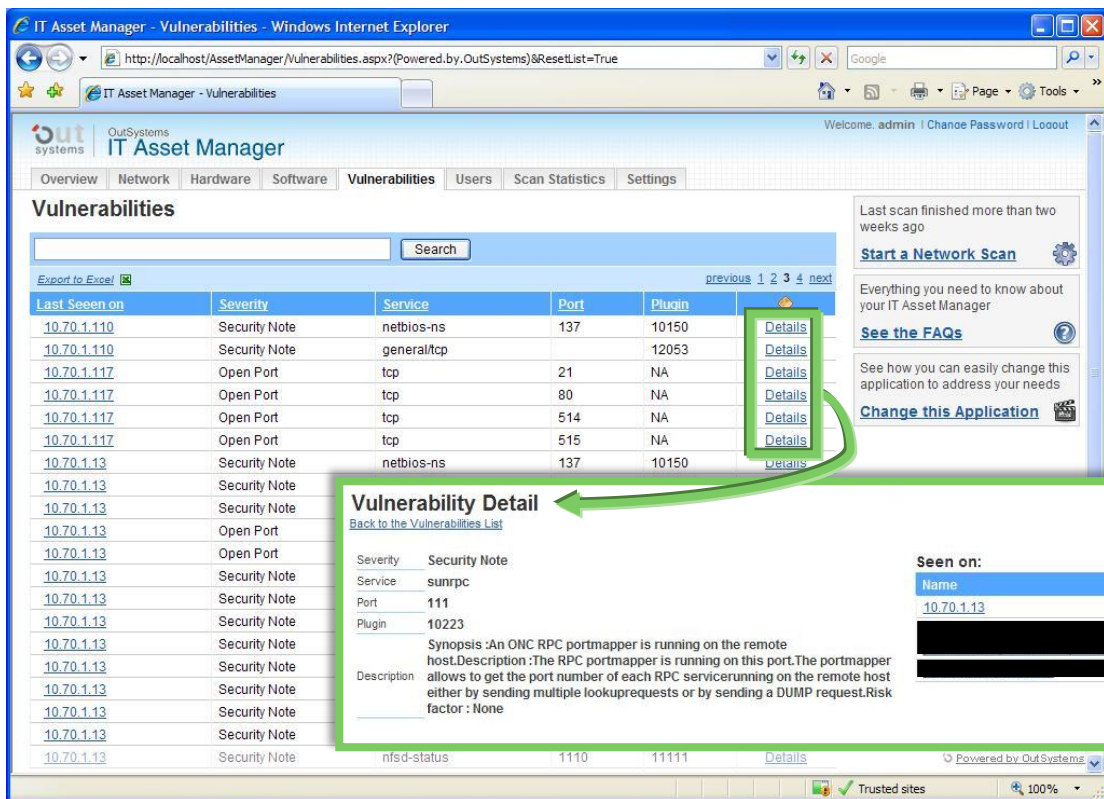

Figure 17: Vulnerability List and Detail

Figure 18 exemplifies how the topology is currently described, presenting a list of the identified network gateways. Figure 19 presents the information a given machine can possibly include.

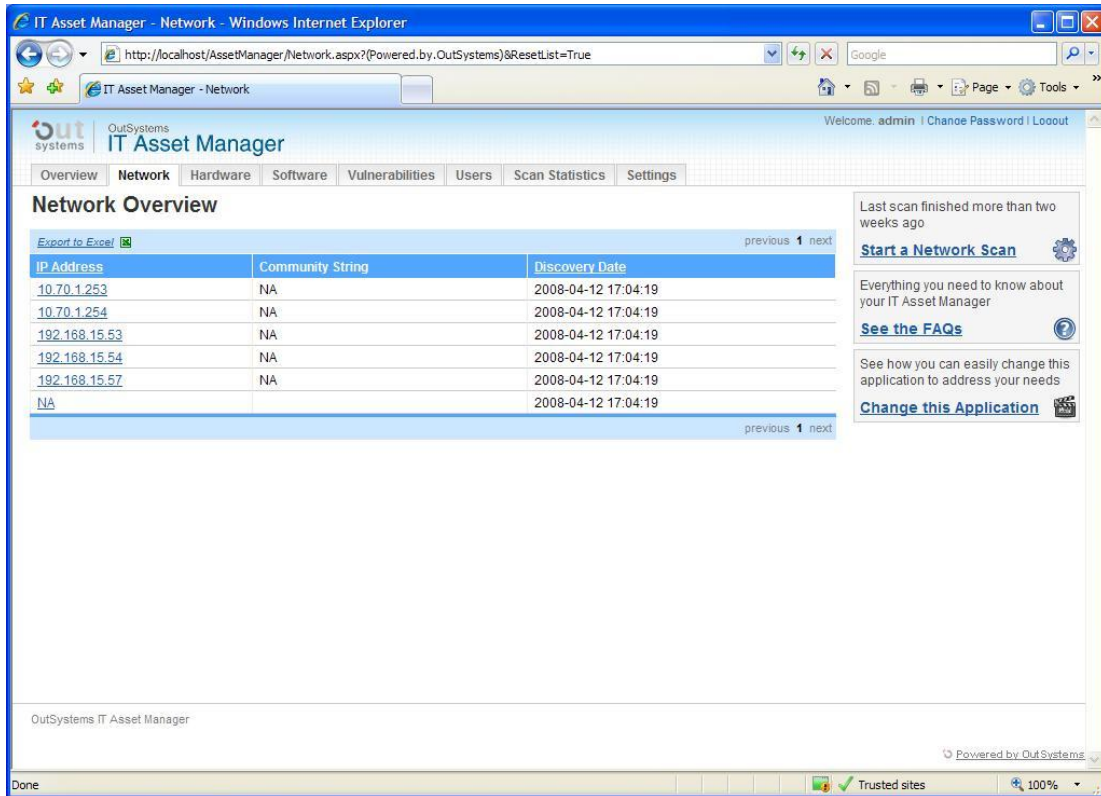

Figure 18: Topology Description

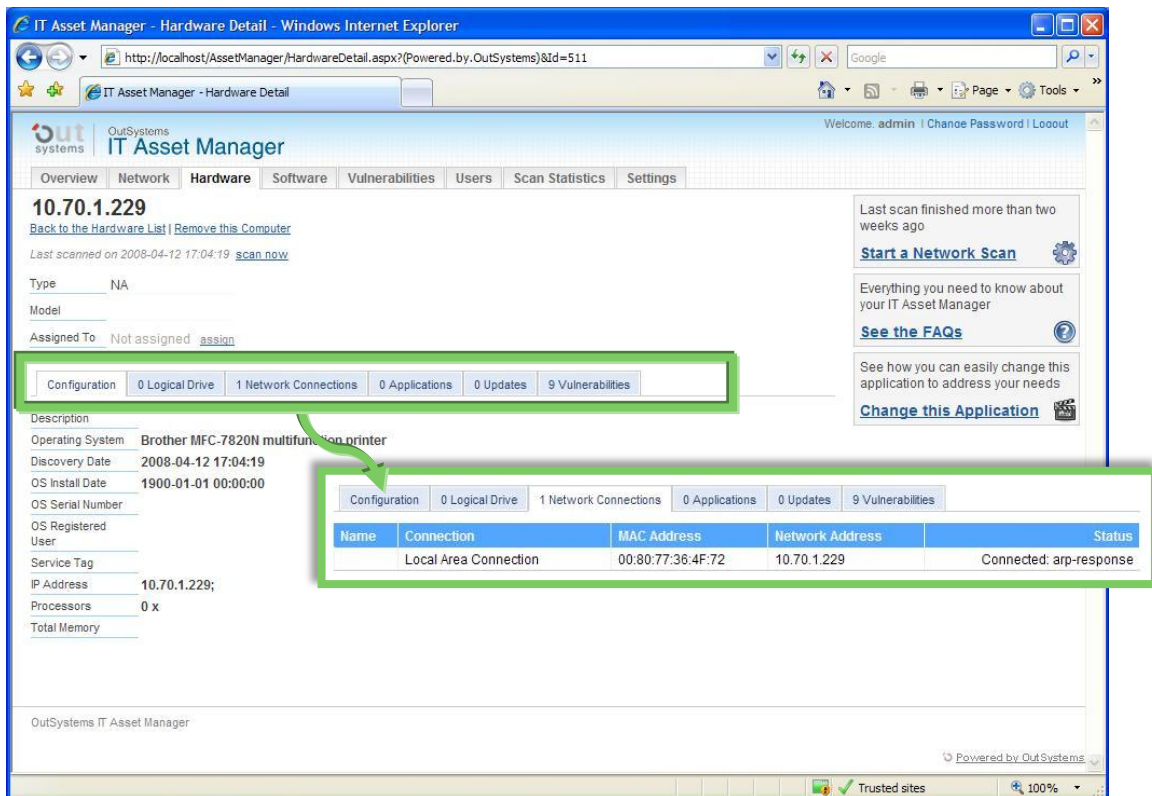

Figure 19: Hardware Detail

Figure 20 shows a network scan statistics exemplar, and Figure 21 illustrates how the user can specify several parameters and input options into the application.

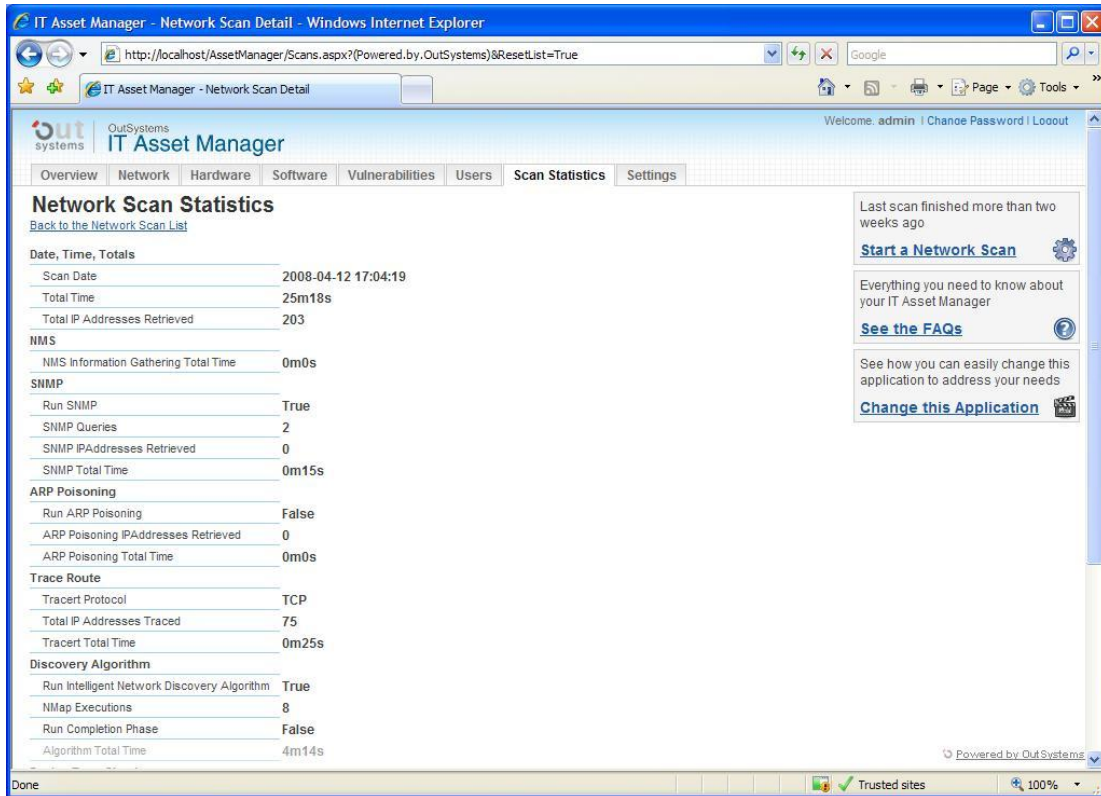

Figure 20: Network Scan Statistics

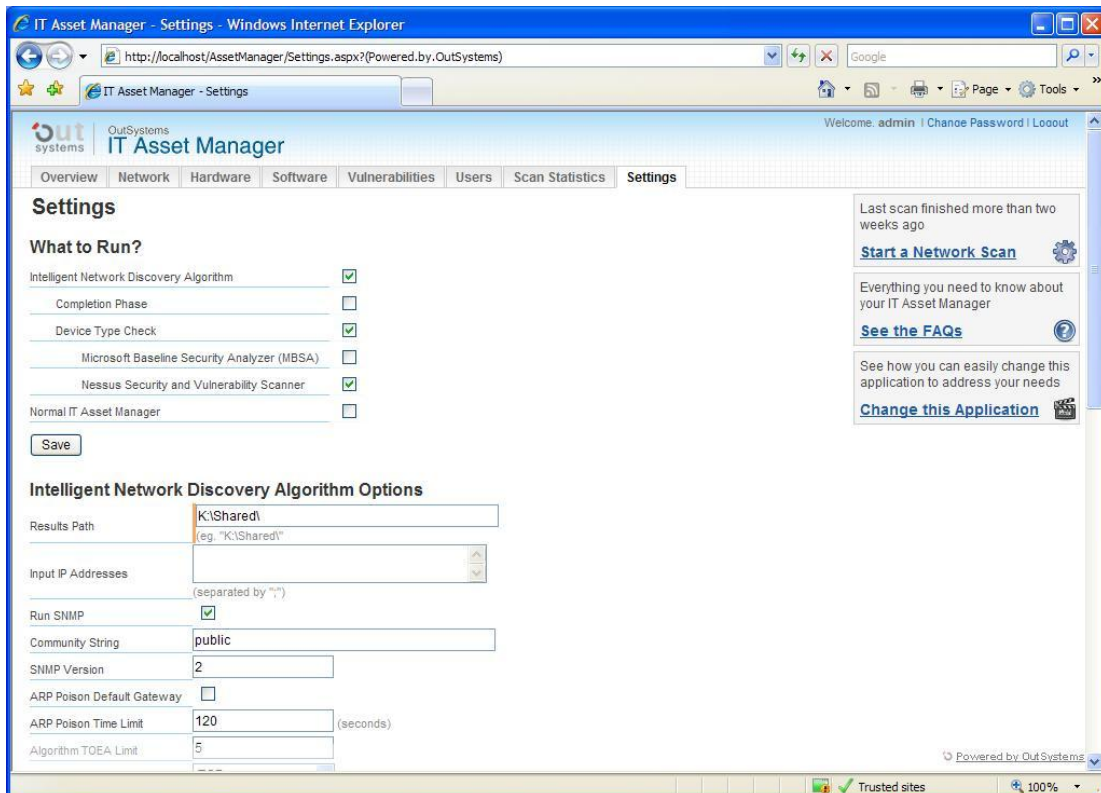

Figure 21: Network Scan Configuration

5.7. TOOLS AND LIBRARIES REQUIRED

Our implementation incorporated several tools and libraries to accomplish the specified requirements. This mentioned integration is demonstrated in Figure 22.

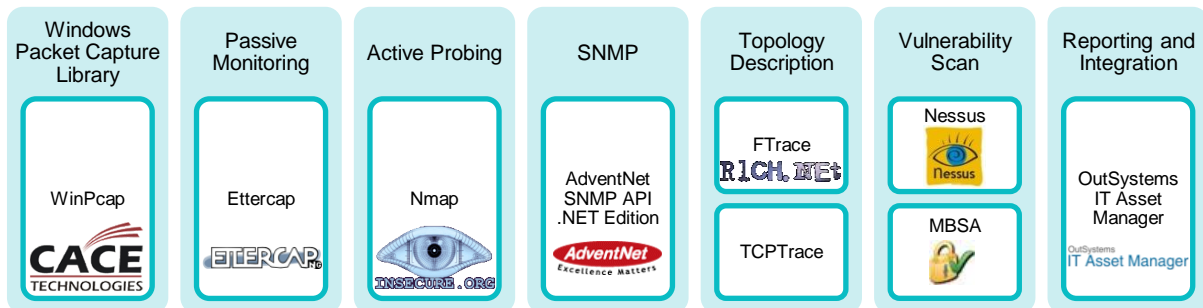

Figure 22: Tools and Libraries Used

The following sections discuss every mandatory application and library not fully described until this point.

5.7.1. WINPCAP

WinPcap is the industry-standard tool for link-layer network access in Windows environments: it allows applications to capture and transmit network packets bypassing the protocol stack, and has additional useful features, including kernel-level packet filtering, a network statistics engine and support for remote packet capture. WinPcap consists of a driver, which extends the operating system to provide low-level network access, and a library, used to easily access the low-level network layers.

Thanks to its set of features, WinPcap is the packet capture and filtering engine of many open source and commercial network tools, including protocol analyzers, network monitors, network intrusion detection systems, sniffers, traffic generators and network testers. Necessarily, almost the entire set of tools we integrated in our implementation requires the installation of WinPcap.

5.7.2. ETTERCAP

Ettercap [63] is an open source software tool for computer network protocol analysis and security cracking. It is capable of intercepting traffic on a network segment, capturing passwords, and conducting man-in-the-middle attacks against a number of common protocols. It features sniffing of live connections, content filtering on the fly, and supports active and passive dissection of many protocols (even ciphered ones).

As Figure 23 [65] exemplifies, the man-in-the-middle attack is able to monitor, filter, modify and edit any traffic moving between the LAN's unsuspecting and inherently trusting computers. In theory, there is nothing to prevent it from filling every computer's ARP cache with entries pointing to it, thus allowing it to effectively become a master hub for all information moving throughout the network.

Figure 23: Man-in-the-Middle Attack [65]

5.7.3. ADVENTNET SNMP API .NET EDITION

AdventNet SNMP API .NET Edition is a comprehensive development toolkit for SNMP-based network management applications. AdventNet's SNMP stack comprises a set of powerful .NET SNMP library to build real-time applications for monitoring and tracking network elements that are reliable and scalable. The library provides ready-made components for trap and table handling, and the basic SNMP operations: SNMP GET, SNMP GETNEXT, SNMP GETBULK, and SNMP SET. These components enable simpler and faster development and deployment of SNMPv1 and SNMPv2c management applications that can be integrated into any network management solution.

5.7.4. FTRACE AND TCPTRACE

Ftrace is an enhanced traceroute application for Windows. It is faster than the standard tracert tool whilst preserving the same command line interface and also providing new options such as UDP support. It features UDP support for getting past routers or firewalls that block ICMP; optional DNS cache file to speed up commonly traced routes; configurable buffer size, pings per hop, TTL and TOS settings; and is faster than Windows standard tracert.exe due to no delay between hops.

TraceTCP is a command line traceroute utility for Windows that uses TCP SYN packets rather than ICMP/UDP packets that the usual implementations use, thus bypassing gateways that block traditional traceroute packets. In addition to providing the functionality of the standard traceroute utility, tracetcp allows a trace to be performed over any TCP port. This allows the discovery of what ports a firewall blocks and also the presence of any transparent proxies that have been put in place.

5.8. SUMMARY

To cover all the proposed requirements, various tools for network discovery and vulnerability scanning were included, as a whole, in the final implemented application. However, it's important to mention that the chosen tools were determined taking into account the best attributes each one has to offer. In addition to the efficient integration of all the proposed mechanisms, a relevant level of intelligence was applied, taking into account the problems described in sections 3.3. and 3.4.

6. EVALUATION

6.1. COMPARISON

After the implementation and development phases, it was necessary to evaluate the framework to ensure that the results meet the requirements originally desired. Table 4 represents the implemented qualities, in order to compare the developed application with several commercially available ones.

Table 4: Evaluation of the Proposed Framework

	Spiceworks	Foresight	Nessus	MBSA	OutSystems IT Asset Manager	Proposed Framework
IP-Based Network Device Discovery	✓	✓	✓	✗	✗	✓
Software Recognition	✓	✗	✗	✗	✓	✓
Patch Management	✓	✗	✗	✓	✓	✓
Service Discovery	✓	✗	✓	✗	✗	✓
No Input Information Required	✗	✗	✗	✗	✗	✓
No Administrator Credentials Required	✗	✗	✓	✗	✗	✓
Doesn't Require SNMP / WMI	✗	✓	✓	✓	✗	✓
No Brute-Force Discovery	✗	✗	✗	-	✗	✓
Passive Monitoring Discovery	✗	✗	✗	✗	✗	✓
Vulnerability Scanner	✗	✓	✓	✓	✗	✓
Network Topology Description	✗	✗	✗	✗	✗	✓
Network Device Discovery Efficiency	*****	*****	***	-	*****	*****

It's important to mention that the "Software Recognition" component can only be performed if the user has specified the proper administration credentials, or by extracting this information via SNMP or WMI for each host. Again, regarding the last measurement component ("Network Device Discovery Efficiency"), only if SNMP or WMI are globally available on the network and administrator credentials are known lets various analyzed tools to have the same level of efficiency as the proposed one. If they aren't, their efficiency and accuracy tend to be null.

6.2. CASE STUDIES

Because some networks could have SNMP widely available on the network while others might have several security systems properly configured, it was important to experiment the application in several networks with different environments to correctly assess the accuracy of the proposed mechanism.

The framework was tested on distinct network infrastructures of three organizations: an official Portuguese government related central authority and two Portuguese institutions of higher education.

On each of the three cases, no network administration credentials were granted. In fact, merely one IP address was given. As a result, it seems that, from the aforesaid available tools and apart from our newly proposed application, Nessus was the only tool that would allow a scan with no configured administrator credentials. In addition, due to the non specification of the network address range, the stated scan had to start just with the current IP address specified. This was an enormous setback for Nessus, as it clearly persuades a network address range as input. On the contrary, the proposed scanning process can therefore employ the intelligent algorithm for network topology discovery (to ingeniously generate the IP ranges to audit), or take advantage of the integrated passive monitoring mechanism.

For the reason that the ARP Poisoning technique can be a truly intrusive method, it was used for a short period of time. Even with this drawback, none of the abovementioned commercial applications included this functionality. In any case, this provided the algorithm some possible IP addresses that are indubitably alive on the network.

Finally, even if a network IP address range was revealed as input, and because all the evaluated tools determine the active network devices by a brute force and sequential scheme, the scanning process would undoubtedly be very inefficient when compared to our approach. Table 5 clearly validates this statement.

Table 5: Case Studies Comparison Results

		Case Study 1	Case Study 2	Case Study 3
Configuration	Administration Credentials Granted			
	Run Passive Monitoring Module (ARP Poisoning)			
	Run Auto Discovery Module (SNMP)			
	Run Device Type Identification and Port Scanning Modules			
	Run Vulnerability Scanner Module			
Results	Passive Monitoring Module (ARP Poisoning)	<ul style="list-style-type: none"> 60 seconds were enough to identify 30 active IP addresses Didn't capture any clear text SNMP community strings 	-	<ul style="list-style-type: none"> 120 seconds were enough to identify 10 active IP addresses Didn't capture any clear text SNMP community strings
	Auto Discovery Module (SNMP)	<ul style="list-style-type: none"> With no divulgation of the community string it used the default ones Ineffective but lasted only 15,6 seconds to perform all (2) queries 	<ul style="list-style-type: none"> With no divulgation of the community string it used the default ones Ineffective but lasted only 13,1 seconds to perform all (2) queries 	<ul style="list-style-type: none"> With no divulgation of the community string it used the default ones Ineffective but lasted only 9,9 seconds to perform all (1) queries
	Device Type Identification and Port Scan Modules	20 minutes	10 minutes	101 minutes
	Vulnerability Scan Module	21 minutes	14 minutes	-
	Devices / Subnets Identified	203 / 5	86 / 3	54 / 2
	Intelligent Host Discovery	4 min 14 sec	2 min 32 sec	3 min 55 sec
	Open Ports / Vulnerabilities	174 / 382	104 / 263	41 / -
Total Duration	46 minutes	27 minutes	105 minutes	

As previously stated, no administrator credentials were granted. A surprisingly good result for the network administrators' perspective is that no SNMP information was gathered using the default protocol community strings. The recursive auto discovery algorithm could therefore influence the whole process to be inefficient. However, as the results confirm, the duration for this process to complete was, on average, an excellent 12.9 seconds. On the contrary, the Passive Monitoring technique was many times considered by the network administrators a method that wouldn't work. The results demonstrate that it did, and even captured a handful of addresses each one added to the Initialization Layer.

The Device Type Checks and Vulnerability Scan modules took a considerably longer time to complete, but given the facts presented in section 3.2.1., our results demonstrate, on average, that the efficiency is in fact improved because the Device Type Checks are performed prior to the Vulnerability Scans. Case Study 3 Device Type Check was the only module that was a considerably time-consuming process – 101 minutes.

3 minutes and 34 seconds was the average duration of the Intelligent Host Discovery component, which is the most stimulating result we could obtain to clearly prove the algorithm's great efficiency.

6.3. CMDB INTEGRATION

Our framework was completely integrated with a CMDB, because of the straightforwardness provided by the integration with the OutSystems platform. The discovered information, being on the CMDB, is readily available for extension to other CMDBs either by direct access to the SQL database, via Web Services (which OutSystems supports), or even through CMDB-CMDB integration using the standard. As this integration has perfectly been realized, it would also be straightforward to incorporate the same level of information with other CMDBs, obviously if they incorporate this integration capability.

Finally, as almost all expensive and complex CMDBs usually include a feature to discover the network's assets, any other CMDB can now use the proposed framework to discover the network as a new component and functionality.

6.4. SUMMARY

The application was successfully tested on three completely different networks, and an historical of each performed scan (containing and relating all the information gathered) can be consulted at any moment in time.

All the proposed objectives have been achieved successfully, and the feedback provided by both the administrators of my case study's networks and my advisors from the consulting firm that collaborated with my MSc Thesis, clearly gave a great credibility to the application and its intrinsic value.

With reference to the implemented intelligent and self-learning algorithm for network topology discovery, it has been proved that it really makes a difference when comparing its performance with a brute force and sequential scan. The algorithm supports the heuristic that network administrators, given an assortment of IP addresses, assign IP addresses to devices in such a way that they are grouped together and in a sequence. If the assignment of the IP addresses is done in this fashion, the algorithm has confirmed to have a tendency to reach an accuracy of 100%, since the intrinsic intelligence of the scanning process, when combined to Nmap's discovery techniques, are together specialized to raise some level of response from nearly all network devices, this way validating its liveliness. If the assignment isn't prepared as a sequential format (e.g. 10.0.1.0/24 and 10.0.77.0/24 are the only present subnets), the TOEA algorithm provides the scan an extra level of inefficiency, which should directly be turned off.

7. CONCLUSION

The main objective of this MSc Thesis is to provide an “all-in-one” vulnerability assessment framework that can sharply determine which addresses to audit and which security probes to perform on each type of device, as efficiency and accuracy are the most important established requirements. It covers a personalized methodology to determine the security state of a given network, by providing a newly intelligent and pioneer approach to network scanning and probing, along with vulnerability identification.

The problems currently identified from individual cases reported in the literature were grouped into two main groups: intelligent network discovery and a customized vulnerability scan. Regarding the network discovery process, the top problems that present solutions have to deal can be described as:

- The existence of several countermeasures that obstruct a completely accurate network discovery process;
- Producing a high disturbance on the network, which can include a full denial of service;
- Requiring several kinds of input information, such as administrator credentials or the network address range;
- High inefficiency;
- The lack of the network topology description.

The present vulnerability scanners also account one specific problem: it can generally be described as the lack of customization in the vulnerability scan practices, which can drastically reduce the time this process needs to take.

In order to achieve the set objectives, we proposed a framework that follows the characteristics identified in the need for a newly vulnerability assessment tool that fitted the needs of the consulting firm that cooperated with my work. This application was implemented according to the requirements raised by analysis of the drawbacks of the commercial tools in their application.

The solution is open and flexible to enable the integration of new probes and tests, and provides a graphical interface to allow the observation, in different levels of detail, of the discovered components and associations between them.

Various tools for network discovery and vulnerability scanning were included as a whole in the final implemented application, and were determined taking into account the best attributes each one has to offer. In addition to the efficient integration of all the proposed mechanisms, a relevant level of intelligence was applied, taking into account the problems described in sections 3.3. and 3.4.

Since the solution was tested in three distinct network environments, it was also possible to collect useful testimonies from their network administrators. Their receptivity has been noticeably positive, both in terms of ease of use and graphical interface. This feedback was essential given the growing interest on their part for constantly improve the application.

7.1. FUTURE WORK

As the popularity of the web increases and web applications become tools of everyday use, the role of web security has been gaining importance as well. The last years have shown a significant increase in the number of web-based attacks. For example, there has been extensive press coverage of recent security incidences involving the loss of sensitive credit card information belonging to millions of customers. Additionally, many web application security vulnerabilities result from generic input validation problems. Examples of such vulnerabilities are SQL injection and Cross-Site Scripting (XSS). Although the majority of web vulnerabilities are easy to understand and to avoid, many web developers are, unfortunately, not security-aware. As a result, there are many vulnerable web sites on the Internet [66].

Web server vulnerability scanners such as Nessus dispose of large repositories of known software flaws. While these tools are valuable components when auditing the security of a web site, they largely lack the ability to identify, *a priori*, unknown instances of vulnerabilities. As a consequence, there is the need for a future scanner that covers a broad range of general classes of vulnerabilities, without specific knowledge of bugs in particular versions of web applications, focusing on the identification of a broad range of general application-level vulnerabilities.

Another current issue is the safeness of the vulnerability assessment [67]: although there are many commercial vulnerability scanning tools, none of them are truly safe. In one study [68], all scanners caused adverse effects on the network servers being tested. One scanner crashed at least five servers during an assessment run. According to Nessus documentation [69], every existing network-based vulnerability scanner comes with the risk of crashing the systems/services being tested, or even worse, leaving permanent damaging side effects. In some sense, these results are not surprising at all, since vulnerability testing packets should behave like real attack packets in order to expose the vulnerabilities. The only difference is that vulnerability testing packets are not supposed to intentionally cause damage to the tested network servers, even though they might do so accidentally.

Safety of vulnerability assessment is a well-known problem to which there is no adequate solution until now [67]. Although some vulnerability scanning tools such as Nessus and Foundstone [49] attempted to mitigate this problem, none of them completely solve it. Even when the “safe scan” option is turned on, some vulnerability testing tools can still crash the servers being tested. For future work, we propose a vulnerability assessment support system which automates the vulnerability testing process while guaranteeing its safety.
